## Collaborators on This Edition

WALLACE D. ARMSTRONG, M.D., PH.D. Head of the Department of Physiological Chemistry, University of Minnesota, Minneapolis, Minnesota.

RICHARD J. BLOCK, PH.D. Lecturer (Professorial Rank), Department of Biochemistry, New York Medical College, New York, N.Y.

GEORGE B. BROWN, PH.D. Professor of Biochemistry, Head of Division of Protein Chemistry, Sloan-Kettering Division of Cornell University Medical College, New York, N.Y.

CARL F. CORI, M.D., Sc.D. Professor of Biochemistry, Washington University School of Medicine, St. Louis, Missouri.

GERTY T. CORI, M.D., Sc.D. Professor of Biochemistry, Washington University School of Medicine, St. Louis, Missouri.

GEORGE R. COWGILL, PH.D., Sc.D. Professor of Nutrition, Department of Physiological Chemistry, Yale University School of Medicine, New Haven, Conn.

WILLIAM J. DARBY, M.D., PH.D. Professor of Biochemistry, Vanderbilt University School of Medicine, Nashville, Tennessee.

HARRY J. DEUEL, JR., PH.D. Dean of Graduate School, University of Southern California, Los Angeles, California.

ROSS A. GORTNER, JR., PH.D. Professor of Biochemistry, Wesleyan University, Middletown, Conn.

PHILIP L. HARRIS, PH.D. Head of Biochemistry Research Department, Distillation Products *industries*, Rochester, N.Y. Associate in Physiology, University of Rochester School of Medicine and Dentistry.

R. H. D. HEARD, PH.D. Associate Professor of Biochemistry, McGill University, Montreal, Canada.

THOMAS H. JUKES, PH.D. Head of Department of Nutrition and Physiology Research, Lederle Laboratories, Pearl River, N.Y.

MAXWELL KARSHAN, PH.D. Associate Professor of Biochemistry, College of Physicians and Surgeons of Columbia University, New York, N.Y.

EDWARD C. KENDALL, PH.D. Visiting Professor in Chemistry, James Forrestal Research Center, Princeton University, Princeton, N.J.

O. L. KLINE, PH.D. Director of Research, Division of Nutrition, Food and Drug Administration, Department of Health, Education, and Welfare, Washington, D.C.

HOWARD BISHOP LEWIS, PH.D.\* John Jacob Abel Professor of Biological Chemistry, University of Michigan Medical School, Ann Arbor, Mich.

HENRY A. MATTILL, PH.D.\* Professor of Biochemistry, State University of Iowa, Iowa City, Iowa.

WILFRIED F. H. M. MOMMAERTS, PH.D. Associate Professor of Biochemistry, Western Reserve University School of Medicine, Cleveland, Ohio.

ARMAND J. QUICK, M.D., PH.D. Professor and Director of the Department of Biochemistry, Marquette University School of Medicine, Milwaukee, Wisconsin.

MARTIN E. REHFUSS, M.D. Professor Emeritus of Clinical Medicine and Sutherland M. Prevost Lecturer in Therapeutics, Director of the Department of Therapeutics, Jefferson Medical College, Philadelphia, Pa.

JOHN G. REINHOLD, PH.D. Associate Professor of Physiological Chemistry and Medicine, University of Pennsylvania Hospital, Philadelphia, Pa.

DAVID SELIGSON, PH.D., M.D. Director of the Division of Biochemistry, Graduate Hospital, Philadelphia, Pa.

EPHRAIM SHORR, M.D. Associate Professor of Medicine, Cornell University Medical College, New York, N.Y. Assistant Attending Physician at New York Hospital, New York, N.Y.

ARTHUR H. SMITH, PH.D. Professor of Physiological Chemistry and Director of Graduate Medical Education, Wayne University College of Medicine, Detroit, Michigan.

ALBERT E. SOBEL, PH.D. Head of Department of Biochemistry, Jewish Hospital of Brooklyn, Brooklyn, N.Y. Adjunct Professor of Chemistry at Polytechnic Institute of Brooklyn. Special Lecturer, New York State University College of Medicine.

HARRY SOBOTKA, PH.D. Head of Department of Chemistry, Mount Sinai Hospital, New York, N.Y.

JAMES B. SUMNER, PH.D. Director of Enzyme Chemistry Laboratory, New York State College of Agriculture, Cornell University, Ithaca, N.Y.

DAVID L. THOMSON, PH.D. Professor of Biochemistry and Dean of Faculty of Graduate Studies and Research, McGill University, Montreal, Canada.

GEORGE WALD, PH.D. Professor of Biology, Harvard University Biological Laboratories, Cambridge, Mass.

BURNHAM S. WALKER, PH.D., M.D. Professor of Biochemistry and Chairman, Division of Medical Sciences in Graduate School, Boston University School of Medicine, Boston, Mass.

JOHN H. YOE, PH.D. Professor of Chemistry, School of Chemistry, University of Virginia, Charlottesville, Virginia.

\* Deceased.

Dedicated  
To the memory of  
LAFAYETTE B. MENDEL,  
Guiding Genius of American Biochemistry  
who fifty years ago inspired the  
First Edition of this work

The Publishers are proud of the long record of continuous authorship of this book under the Blakiston imprint and are grateful for the professional acceptance which has made a Thirteenth Edition possible.

# Preface

It is with a mingled sense of pride and humility that the senior author presents this—the Thirteenth Edition of PRACTICAL PHYSIOLOGICAL CHEMISTRY. To have been actively engaged in the authorship of successive editions of a textbook for fifty years is a privilege granted to few in the annals of medical publication. For this good fortune, I am deeply grateful.

Perhaps even more than some of its predecessors, this Edition has undergone extensive revision and expansion. The proportion of the book devoted to textual material, as distinguished from experiments and procedures, has increased to the extent that it now accounts for about one-half of the entire volume. Certain chapters, such as those dealing with Nucleic Acids and Nucleoproteins (Chapter 7), Milk (Chapter 8), Muscular Tissue (Chapter 10), Enzymes and Their Action (Chapter 12), and Isotopes (Chapter 32), have been exhaustively rewritten. To other chapters major additions have been made, as for example Chapter 18 to which a section on Liver Function has been added, and Chapter 23 which now contains a section on Microclinical Chemistry.

Try as its author will, no textbook in such a rapidly developing area of research as biochemistry, can possibly be kept strictly up to the minute; it must inevitably run a losing race with the periodical literature. Nevertheless the authors of this volume and their collaborators have expended every effort in the direction of supplementing established knowledge with current facts, theories, and hypotheses, insofar as this is possible, with full awareness that in some respects, obsolescence commences with the date of publication (if not before). This may be of more concern to the research worker than to the student and for that reason the former should have recourse to original journals such as those cited profusely throughout this book.

An endeavor has been made to keep pace with current advances in the many fields of biochemistry which are benefiting from the availability of advanced techniques and instrumentation. Symbolic of these innovations, which give promise of epoch-making advances, is the replacement of the time-honored Frontispiece of this book depicting absorption spectra of the blood pigments and their derivatives with a new color plate showing a two-dimensional chromatogram of a protein hydrolyzate. For this illustration the authors are greatly indebted to Dr. A. J. P. Martin of the National Institute for Medical Research, London, and to the publishers of ENDEAVOUR, The Imperial Chemical Industries, Ltd., London.

Experimental, analytical, and preparative methods employing these newer techniques and research tools are scattered through various chapters of the book. Only a brief summary can be given here. The student and teacher of biochemistry will find of general interest the new material on electrophoresis; the ultracentrifuge; ion-exchange resins; column and

paper chromatography; countercurrent distribution; the helical structure of proteins; the polypeptide sequence of insulin; the chemistry of the corticosteroids; the synthesis of oxytocin; the chemistry and metabolism of nucleoproteins, nucleic acids and derivatives; the role of muscle proteins and ATP in muscle contraction; the biochemistry of bone and teeth; the kinetics of enzyme action; theories of blood clotting; the intermediary metabolism of carbohydrates, fats, and amino acids, including the role of coenzyme A and "one-carbon fragments"; the cobalamins, thioctic acid, leucovorin, and related factors; isotopes and their use in biochemical research; new material on antibiotics; and much more.

The teacher will find many new experiments suitable for class use, some of which were developed specifically for this Edition, illustrating such topics as paper and column chromatographic separation of amino acids, purine nucleotides, etc.; countercurrent distribution; myosin and actin; glycogen storage and depletion; determination of blood volume with isotope-labeled red blood cells; blood coagulation and prothrombin time; liver function tests; and many others.

The clinician will find new and authoritative sections on: the biochemistry of liver disease; the biochemistry of the bones and teeth, and the use of fluoride in the prevention of dental decay; isotopes and their use in medicine; dextran; cholinesterase; adrenal cortical and pituitary hormones; and the nutritive value of milk. Clinical chemical procedures not found in the previous Editions include the more important liver-function tests (thymol turbidity, cephalin-cholesterol flocculation, bromsulfalein, etc.); determination of blood protein-bound iodine, of blood cholinesterase, and of blood sodium and potassium by flame photometry; and others. A unique and valuable section has also been added on the use of micromethods in clinical chemistry, with detailed procedures and descriptions of apparatus.

Revisions of PRACTICAL PHYSIOLOGICAL CHEMISTRY have never been a one-man job. The success and prestige of the book has been due in no small measure to the fine cooperation shown by many teachers and investigators in the medical and biochemical fields. A list of those who have participated in some degree on one or more editions would read like a combination of WHO'S WHO and WHO WAS WHO in these professions.

In the elaboration of this Edition the authors feel signally honored to have enjoyed the cooperation of many distinguished scientists and educators. To credit them individually with specific contributions would fail to do justice to those whose advice and assistance is reflected in several places, if not generally, throughout the book.

In consequence, deep gratitude is expressed here on behalf of my associated co-authors and myself for major contributions and assistance of the collaborators whose names and affiliations are listed immediately preceding this Preface. Without the splendid and gracious help of these eminent biochemists and physicians it would have been infinitely more difficult to produce what we believe is the finest of a long series of revisions.

Special acknowledgment and thanks are due the following eminent experts and teachers whose generous assistance, both solicited and unsolicited, while not quite as extensive as that of the aforementioned col-

laborators was none the less welcome: Dr. Zoe E. Anderson, Director of the National Dairy Council's Research and Nutrition Service; Dr. A. K. Balls, Professor of Enzyme Chemistry, Purdue University; Dr. Albert L. Chaney, Director of the Albert L. Chaney Chemical Laboratory, Glendale, Cal.; Dr. L. C. Craig, Member, Rockefeller Institute for Medical Research; Dr. Alexander L. Dounce, Assistant Professor of Biochemistry, University of Rochester School of Medicine and Dentistry; Dr. Theodore E. Friedemann, Scientific Director, Medical Nutrition Laboratory, Fitzsimons Army Hospital, Denver, Col.; Dr. Linus Pauling, Professor of Chemistry, California Institute of Technology; Dr. Kurt G. Stern, Adjunct Professor of Biochemistry, Polytechnic Institute of Brooklyn; Dr. Henry Tauber, Associate Professor of Experimental Medicine, School of Public Health, University of North Carolina; Dr. Oscar Touster, Associate Professor of Biochemistry, Vanderbilt University School of Medicine; Dr. Everett C. Cogbill and Mr. Richard M. Rush of the University of Virginia; and Dr. M. A. Derow of Boston University.

Once again it is my pleasure to pay tribute to the skill and untiring efforts of my associates, Dr. Bernard L. Oser, whose more than quarter-century association with this book is well known to its friends, and Dr. William H. Summerson, whose long experience as a teacher and investigator at Cornell Medical College preceding our association, eminently qualified him for the important role he has assumed as a co-author.

For their assistance in matters editorial the authors are particularly indebted to Mrs. Eunice Stevens, editor-in-chief of Blakiston, and her able and conscientious associate editor, Mr. Barney Pisha. Their efforts in standardizing style and typography are reflected in the enhanced appearance of this completely reset edition. In this connection reference may be made to questions of spelling and nomenclature where uniformity of practice in the scientific literature has yet to be achieved. Since the American Chemical Society, more than any other single organization, has been concerned with standardization in this field, the recommendations of that organization have been adopted despite the risk, in some instances, of jarring the sensibilities of a few readers (and occasionally of a co-author). While appreciation is expressed to the publisher's and printer's staffs for their careful efforts in proofreading, the authors assume full responsibility for such errors and oversights as will inevitably be discovered by sharp-eyed readers.

Appropriate acknowledgment has been made through this edition to the numerous authors, publishers and instrument and apparatus companies who so graciously granted permission for the use of illustrations, tables, or other copyrighted material. Appreciation is expressed here for these courtesies and, in the unlikely event that acknowledgment has been omitted in the specific places where such material has been used, the authors claim human frailty and apologize for these oversights.

Finally, the authors are deeply appreciative of the patience and co-operation of the Maple Press whose fine craftsmanship has made possible the production of this attractive volume.

I trust I will be pardoned for concluding this Preface with a short personal note.

The manuscript of the First Edition of this book was drafted high up in the old Hare Laboratory of the Medical School of the University of Pennsylvania, amid the stimulating fragrance of the Department of Anatomy. It served as the basis for a course of instruction even before the edition was in print. Now, a half-century later, and thanks to its friendly reception by the profession, the Thirteenth Edition has rolled off the press.

Among those to whom I was indebted for its genesis, first place must go to the late Professor Lafayette B. Mendel for it was he who generated the spark of inspiration. The value of Dr. Mendel's suggestions and criticism of the manuscript of several editions was great indeed. His wonderful letters, written in long hand with purple ink and crammed full of ideas, references, and suggestions were of incalculable aid. These missives were never less than six pages long and often twice as long. The First Edition was thus, quite naturally, based on the courses as given at Yale University, with minor features as adopted at Columbia University (College of Physicians and Surgeons) where I passed my first teaching assignment (1901-1903) under Professor William J. Gies. Dr. Mendel's interest in the book never flagged. It is therefore fitting and proper that to Dr. Lafayette B. Mendel, guide, philosopher, and friend of many an outstanding biochemist as he was of the senior author, should be dedicated this "Golden Anniversary" Edition of PRACTICAL PHYSIOLOGICAL CHEMISTRY.

PHILIP B. HAWK

MIAMI BEACH, FLORIDA

## Preface to the First Edition

The plan followed in the presentation of the subject of this volume is rather different, so far as the author is aware, from that set forth in any similar volume. This plan, however, he feels to be a logical one and has followed it with satisfactory results during a period of three years in his own classes at the University of Pennsylvania. The main point in which the plan of the author differs from those previously proposed is in the treatment of the food stuffs and their digestion.

In Chapter IV the "Decomposition Products of Proteids" has been treated although it is impracticable to include the study of this topic in the ordinary course in practical physiological chemistry. For the specimens of the decomposition products, the crystalline forms of which are reproduced by original drawings or by microphotographs, the author is indebted to Dr. Thomas B. Osborne, of New Haven, Conn.

Because of the increasing importance attached to the examination of feces for purposes of diagnosis, the author has devoted a chapter to this subject. He feels that a careful study of this topic deserves to be included in the courses in practical physiological chemistry, of medical schools in particular. The subject of *solid tissues* (Chapters XIII, XIV and XV) has also been somewhat more fully treated than has generally been customary in books of this character.

The author is deeply indebted to Professor Lafayette B. Mendel, of Yale University, for his careful criticism of the manuscript and to Professor John Marshall, of the University of Pennsylvania, for his painstaking revision of the proof. He also wishes to express his gratitude to Dr. David L. Edsall for his criticism of the clinical portion of the volume; to Dr. Otto Folin for suggestions regarding several of his quantitative methods, and to Mr. John T. Thomson for assistance in proof reading.

For the micro-photographs of oxyhaemoglobin and haemin reproduced in Chapter XI the author is indebted to Professor E. T. Reichert, of the University of Pennsylvania, who, in collaboration with Professor A. P. Brown, of the University of Pennsylvania, is making a very extended investigation into the crystalline forms of biochemic substances. The micro-photograph of allantoin was kindly furnished by Professor Mendel. The author is also indebted for suggestions and assistance received from the lectures and published writings of numerous authors and investigators.

The original drawings of the volume were made by Mr. Louis Schmidt whose eminently satisfactory efforts are highly appreciated by the author.

PHILIP B. HAWK

# I

## Physicochemical Principles

Living matter differs from nonliving in its possession of certain characteristic properties such as growth, reproduction, respiration, and motion. The science of physiological chemistry deals with the application of chemical and physicochemical principles and methods to the study of these phenomena. In the early days of the science this meant the analysis of foods entering the organism and of excreta leaving it; it involved the study of the composition of the various tissues and organs of the body, the blood, the digestive secretions, etc. In this way a great deal of information has been collected concerning the composition of living matter and the fate of the substances that are necessary for continuance of life and growth. Although far from complete these researches have progressed to the point where we now possess a fairly comprehensive picture of the gross changes that take place in protoplasm.

The experimental methods used, however, for the most part involved the destruction of the living cell. In recent years the emphasis has been placed on the mechanisms concerned in the reactions of the living protoplasm itself. Since protoplasm is largely water, this requires a study of the nature of solutions and the complex behavior of mixtures of electrolytes. Since the physical basis of protoplasm is colloidal in character, a study of the peculiar structure and properties of colloidal solutions is also necessary. Some of the more important physicochemical principles that are finding wide and fruitful application in the study of life phenomena are discussed briefly in the following pages.

### THE COLLOIDAL STATE

**True and Colloidal Solutions.** Thomas Graham in 1861 classified all substances into two groups, crystalloids and colloids, depending upon their ability to diffuse through membranes such as parchment. According to Graham, crystalloids readily passed through parchment membranes while colloids did not. We now recognize that matter cannot be classified in this manner since many typical colloids, such as certain proteins, are crystallizable, and practically all crystalloids may, under proper conditions, be brought into the colloidal state.

According to modern concepts, colloidal solutions, instead of being solutions of particular types of matter, are solutions with a characteristic kind of structure. Substances such as glucose or sodium chloride, which form true solutions in water, disintegrate, when dissolved, into individual molecules or ions which are less than  $1\text{ m}\mu$  (1 millionth mm.) in diameter.

The smallest particle that can be seen with a high-power light microscope has a diameter of about  $200\text{ m}\mu$ . By means of an electron microscope, particles with a diameter as small as  $10\text{ m}\mu$  are readily made visible. When the particles of solute are larger than  $200\text{ m}\mu$  they are said to be in suspension; on standing such particles will gradually separate out. When, however, the solute is dispersed into particles which are intermediate in size between ordinary molecules such as exist in true solutions and the coarse particles found in suspensions, it is said to be in the colloidal state, and solutions containing particles of that size are known as *colloidal solutions* or *sols*. Sols which have become jellylike are called *gels*.

Colloidal solutions, true solutions, and suspensions thus differ from each other fundamentally only in the size of the particles of *solute* (the *disperse phase*) dispersed in the *solvent* (the *dispersion medium*). Because of the dimensions of the disperse phase, colloidal solutions exhibit certain characteristic and unique properties (to be discussed in later sections) which confer upon them their great importance in the structure of living protoplasm. This importance resides in the fact that protoplasm is considered to be a complex system containing many different crystalloidal and colloidal components. Although the structure and properties of this system are too complex to permit exact characterization in the present state of our knowledge, we may gain an insight into these questions by a study of similar, though very much simpler, colloidal systems such as are discussed below.

**Preparation of Colloidal Solutions.** The relationship between colloidal solutions, true solutions, and suspensions indicated above suggests two general methods by which colloidal solutions may be prepared. These methods are classified as (1) condensation and (2) dispersion methods, depending upon whether the colloidal particles are formed by aggregation of individual molecules or by disintegration of coarse particles of matter.

**CONDENSATION METHODS.** The principles underlying the preparation of colloidal solutions by condensation methods are similar to those involved in ordinary precipitation reactions. In both processes the solution is permitted to become supersaturated with respect to some particular substance. Such supersaturated solutions, in the presence of suitable condensation nuclei, develop molecular aggregates which continue to increase in size as long as any available material remains in solution. In precipitation reactions this process of growth continues until the particles become visible in a microscope or to the naked eye when they flocculate from solution. By proper regulation of the experimental conditions, which differ for different substances and procedures, the growth of molecular aggregates may be checked when the particles attain the size characteristic of the colloidal state, thus forming colloidal solutions. Whether a particular reaction will lead to the formation of a colloidal solution or a visible precipitate depends, therefore, entirely upon the conditions under which the experiment is carried out. Von Weimarn, who studied this question very extensively, showed that by merely varying the concentrations of  $\text{Ba}(\text{CNS})_2$  and  $\text{MnSO}_4$  from  $\text{N}/20,000$  to  $7\text{ N}$ , the form of the  $\text{BaSO}_4$  precipitated could be made to vary from large crystals to a colloidal gel. The colloidal state, as indicated in the following scheme, is merely an

intermediate stage between coarse precipitates and true solutions which may be approached, under proper conditions, from either direction.

*Condensation Methods*→

| <i>True Solutions</i>            | <i>Colloidal Solutions</i>            | <i>Suspensions</i>                    |
|----------------------------------|---------------------------------------|---------------------------------------|
| Molecules and Ions               | Molecular Aggregates                  | Molecular Aggregates                  |
| Diameter: Less than<br>1 m $\mu$ | Diameter: 1 m $\mu$ to<br>200 m $\mu$ | Diameter: Greater<br>than 200 m $\mu$ |
|                                  |                                       | ← <i>Dispersion Methods</i>           |

Most of the inorganic colloids may be formed by condensation methods involving such reactions as reduction, oxidation, hydrolysis, and double decomposition. Thus if a dilute solution of gold chloride is treated with formaldehyde under proper conditions, the gold ions are reduced to atoms of gold which then aggregate into particles of colloidal size. Practically all of the metals yield colloidal solutions under similar conditions. Boiling a very dilute solution of ferric chloride results in hydrolysis of this salt with the formation of a colloidal solution of ferric hydroxide. Similar solutions may be obtained by using salts of Cr, Al, or Sn. A dilute solution of arsenious oxide in water, when treated with hydrogen sulfide, undergoes double decomposition with the formation of colloidal arsenious sulfide. In the preparation of colloidal solutions by these methods it is essential that the reactions used do not lead to the formation of soluble, strong electrolytes. This condition is important because colloidal solutions of the type discussed here are extremely sensitive to small amounts of electrolytes, which cause aggregation of the colloidal particles into larger particles which precipitate out of solution.

**DISPERSION METHODS.** The dispersion methods for preparing colloidal solutions involve, as indicated above, the subdivision of coarse material into particles of colloidal size under conditions which will prevent coalescence of those particles. Many substances may be reduced to approximately colloidal size by grinding in a colloid mill, which consists essentially of two flat metal plates placed almost in contact and rotated at very high speeds in opposite directions. Colloidal solutions of most of the metals may be prepared by producing an electric arc between electrodes of the metal held under water or some other suitable liquid. It is quite probable that this method involves some condensation of metal vapors as well as disintegration of the metal itself. Solutions prepared by either of these methods will gradually flocculate unless some stabilizing agents are added to prevent coalescence of the particles. For this purpose use is made of certain substances, either electrolytes or other colloids, called peptizing agents. The electrolytes usually act by conferring an electrical charge on the colloidal particle, which is an essential condition for stability of colloidal solutions of this class. Peptizing colloids, also called protective colloids, apparently form a film about the individual particles, which converts them into particles resembling the protective agent in stability and other properties.

**General Properties of Colloidal Solutions.** It has already been pointed out that the essential difference between colloidal and true solutions lies in the size of the particles of solute dispersed in the solvent.

Although the particles in a colloidal solution are too small to be retained by ordinary filter paper, they are too large to pass through such membranes as collodion, parchment, or cellophane, which are permeable to most substances in true solution. This inability of the colloidal particles to diffuse through certain membranes is made use of in the process known as *dialysis*, by which colloidal solutions may be freed from noncolloidal impurities. The solution is placed in a suitable dialyzing bag and is suspended in a large volume of distilled water which is changed at frequent intervals until the liquid inside the bag no longer gives a test for the particular substance to be removed. This process of dialysis is used extensively in the preparation of salt-free solutions of such biological colloids as the proteins. Last traces of electrolytes may be removed by the process known as *electrodialysis*, in which an electrical current is passed through the solution in a suitably designed apparatus.

If a solution containing colloidal particles is forced through a suitable membrane by pressure, the membrane becomes an ultrafilter, and the colloidal particles are separated from the solution. This process is called *ultrafiltration*. By this means it is possible to separate the crystalloidal and colloidal components of such a fluid as blood plasma, for example. Furthermore it is possible to prepare membranes containing pores of almost any desired size, so that colloidal particles of any particular size may be separated from smaller particles as well as from material in true solution.

Another widely used method for separating colloidal particles of different sizes is based upon the use of the high-speed centrifuge or *ultracentrifuge*. This apparatus, originally developed by Svedberg for the study of particle size in suspensions of inorganic colloids, has found extended application to the problems of protein and virus chemistry by Svedberg and many others, until today it is a fundamental research instrument in these fields. With this instrument a sedimenting force up to several hundred thousand times the force of gravity can be applied to particles in colloidal suspension. Naturally the heavier particles will settle out of the solution under these conditions faster than the lighter or smaller particles, and the actual separation and isolation of individual colloidal substances has been achieved in this way. Furthermore by the use of suitable optical devices it is possible to follow the rate of settling of the various types of colloidal particles which may be present, and thus establish not only whether the disperse phase consists of colloidal particles of several different sizes (*heterogeneous*) or of only one size (*homogeneous*), but also the average size of the particles themselves. If it can be shown that the colloidal particle is a single molecule of the substance, the particle size then becomes a measure of the molecular weight of the substance. This method of approach has found particular application in the field of protein chemistry.

The sedimentation of a particle under stated conditions may be characterized by the *sedimentation constant*,  $s$ , defined as

$$s = \frac{dx/dt}{x\omega^2}$$

where  $dx/dt$  is the rate of settling of the particle per unit time at a distance  $x$  from the center of rotation of the centrifuge, and  $\omega$  is the angular velocity in radians per second. Since the numerical value of  $s$  is usually very low—around  $1 \times 10^{-13}$  for proteins—sedimentation constants are commonly expressed in terms of a unit, the *Svedberg*,  $S$ , which equals  $s$  multiplied by  $1 \times 10^{13}$ .

The relation between the sedimentation constant and the molecular weight under ideal conditions is given by the following expression:

$$M = s \cdot \frac{RT}{D(1 - \bar{v}d_m)}$$

where  $M$  is molecular weight,  $R$  is the gas constant,  $T$  the absolute temperature,  $D$  the diffusion constant,  $\bar{v}$  the partial specific volume of the substance (the volume occupied by one gram of substance at infinite dilution in the solvent) and  $d_m$  the solvent density. This equation requires separate determination of the diffusion constant  $D$ ; errors in  $D$  will be reflected in the value for the molecular weight. Nevertheless the equation, suitably corrected for deviations from ideal conditions, has been widely used. Examples of the molecular weights of proteins determined by sedimentation velocity will be found in Chapter 5.

An alternative procedure for the determination of particle size or molecular weight in the ultracentrifuge is based upon the attainment of a *sedimentation equilibrium*. In this the rate of settling of the particles is established at such a point that it exactly equals the opposing force of diffusion, which tends to redistribute the solute throughout the solvent. Under these conditions the molecular weight is obtained by means of the equation:

$$M = \frac{2RT \ln \frac{C_2}{C_1}}{\omega^2(1 - \bar{v}d_m)(x_2^2 - x_1^2)}$$

where  $C_1$  and  $C_2$  are the concentrations at distances  $x_1$  and  $x_2$ , respectively, from the center of rotation. (The symbol “ln” stands for the natural logarithm.) The value of the diffusion constant is not required in this method, and this is an advantage. On the other hand, precise establishment of sedimentation equilibrium requires careful control over sedimentation rate for relatively long periods of time. In general, molecular weights determined by sedimentation equilibrium differ but slightly from those obtained by sedimentation velocity.

By noting and measuring deviations from the equations just presented, which are based upon spherical particles obeying the gas laws, information concerning not only the size but also the shape of particles may be obtained. In the case of proteins, variation in the value of the sedimentation constant with concentration has been interpreted in terms of equilibrium between monomeric and dimeric forms of the protein molecule.

Since the particles in a colloidal solution consist either of very large molecules or of aggregates of large numbers of individual molecules, it follows that a colloidal solution will contain only a minute fraction of

the number of particles present in a true solution of the same concentration. Such physicochemical properties of solutions as vapor pressure and osmotic pressure depend almost entirely upon the number of particles in solution, the chemical nature of these particles being immaterial. Colloidal solutions, with their comparatively small number of particles, therefore exhibit only very small osmotic pressures; and their vapor pressures, as well as related boiling and freezing points, are practically the same as those of the pure dispersion medium.

If a concentrated beam of light is passed through a colloidal solution and viewed at right angles, its path through the solution is plainly visible as a milky turbidity. True solutions under similar conditions appear optically void. This phenomenon, known as the Tyndall effect, is due to the reflection and scattering of the light by the particles in solution and is similar to that observed when a beam of sunlight passes through the dust-laden atmosphere of a darkened room.

Siedentopf and Zsigmondy, in 1903, developed the *ultramicroscope*, in which a very fine, intense beam of light is focused in a colloidal solution and its path observed with a microscope placed at right angles to the beam. The true nature of the Tyndall effect becomes apparent when colloidal solutions are viewed with the ultramicroscope. It is then observed that the Tyndall light is composed of individual points of light, each point representing light reflected by an individual particle. Colloidal solutions are thus shown to consist of discrete particles suspended in the dispersion medium. When viewed through the ultramicroscope the particles in a colloidal solution are seen to be in a continual state of violent vibratory motion. This phenomenon is known as the *Brownian movement* and is due to bombardment of the particles of disperse phase by the molecules of the solvent.

Colloidal particles ordinarily carry electrical charges which are considered to be distributed over the surface of the entire particle. Because of the presence of these charges the particles in a colloidal solution migrate toward one of the poles in an electrical field, the process being known as *cataphoresis* or, more commonly, *electrophoresis*.

The distance  $x$  through which a particular colloidal particle moves under the influence of an electric current is proportional to the time  $t$  and to the potential gradient  $E$  at the spot where the particle is.  $E$  in turn depends upon the current  $i$ , the conductivity of the solution  $\lambda$ , and the cross-sectional area  $q$  of the solution at this point. The proportionality constant is known as the electrophoretic mobility  $\mu$ . Hence  $\mu = x/tE = x/t \times q\lambda/i$ . The dimensions of  $\mu$  are therefore square centimeters per volt per second. The distance  $x$  is usually measured by the so-called moving boundary method. In the version of this procedure developed by Tiselius and widely used, the colloidal solution is brought into contact with the solvent alone by a process of layering that uses a sectioned U-tube (see Fig. 105, p. 461) to produce a sharp boundary between the colloid-containing solution and the solvent alone, although the two solutions are continuous through the solvent itself. An electric current passing across this boundary will carry the colloidal particles into the solvent or away from it, depending upon the polarity of the current

and the charge on the particles. If all the particles are similar with respect to charge, mass, and shape, they will move as a unit, so that in effect the boundary itself will move and will remain sharp. Optical or other methods for measuring the movement of the boundary will then establish the rate of movement of the colloidal material. If the colloidal solution is composed of various types of particles with differing electrophoretic mobilities, several boundaries or zones will develop, moving at different rates. In this way a mixture of colloidal substances may be characterized, and under suitable conditions the components may actually be separated from one another.

A simplified form of electrophoresis apparatus suitable for clinical and other uses employs a strip of filter paper (*paper electrophoresis*) saturated with solvent (electrolyte) and attached to two electrodes. The colloidal solution is deposited on the filter paper at one spot, the filter-paper matrix tending to localize the added material. Under the influence of an electric current the colloidal particles present will migrate along the paper strip in bands in much the same manner as that described above for the Tiselius procedure, and these bands may be visualized by suitable procedures (see Fig. 57, p. 184).

Like the ultracentrifuge mentioned above, electrophoresis in the study of colloidal systems has found application not only in isolating individual colloidal substances from mixtures but also in characterizing the components of complex natural colloidal solutions such as the proteins of blood plasma.

**Classification of Colloidal Solutions.** Colloidal solutions are classified into (1) suspensoids, or lyophobic colloids, and (2) emulsoids, or lyophilic colloids. The *suspensoids* include such colloidal solutions as those formed by the metals, inorganic salts, etc., and their preparation usually requires special methods such as the dispersion and condensation methods described above. They are called *lyophobic* colloids because there is no affinity between the particles of disperse phase and the dispersion medium. In many of their physical properties, such as viscosity, suspensoids differ only slightly from the pure dispersion medium. The particles of a suspensoid carry a definite electrical charge which may be changed only by very special methods. Suspensoids are flocculated by very small quantities of electrolytes, and when so precipitated cannot ordinarily be brought back into colloidal solution. The precipitation of suspensoids is therefore irreversible. When viewed with the ultramicroscope suspensoids are seen to contain well-differentiated particles in vigorous Brownian movement.

The *emulsoids*, since they include the proteins and the higher carbohydrates, are of much greater biological importance and interest than the suspensoids. They are called *lyophilic* (or *hydrophilic* when the dispersion medium is water) colloids because they have a high affinity for the dispersion medium. The viscosity of emulsoids is usually much higher than that of the dispersion medium. The particles carry electrical charges which, in the case of proteins, for example, may be changed in sign or magnitude by such simple measures as changing the acidity or alkalinity of the solution. The emulsoids require large amounts of electrolytes for their precipitation and when precipitated may usually be brought back into colloidal solu-

tion by the addition of fresh solvent. The precipitation of emulsoids is therefore reversible.

Emulsoids and suspensoids thus exhibit essential differences in their behavior toward the solvent and in their sensitivity to small amounts of electrolytes. The stability of suspensoids depends entirely upon the charges on the particles, which permit them to repel each other and thus prevent aggregation into coarser particles. If the charges on the suspensoid particles are neutralized, or reduced below a certain critical value, the particles coalesce and precipitate. The sensitivity of suspensoids to small amounts of electrolytes is therefore due to the fact that electrolytes neutralize or reduce the charges on the particles and thereby remove the

FIG. 1. STABILITY OF SUSPENSIDS AND EMULSIDS.

force which is ordinarily sufficient to prevent aggregation and flocculation. In this precipitating action of electrolytes on suspensoids, the active ion is the one whose charge is opposite in sign to that carried by the suspensoid.

On the other hand, emulsoids possess two stability factors—charge and hydration—either of which is capable of preventing the aggregation and flocculation of the colloid. Neutralization of the charges on the emulsoid converts it into a neutral, or isoelectric, colloid which is perfectly stable as long as the particles remain hydrated. Dehydration of a charged, electrolyte-free emulsoid (e.g., by the addition of a dehydrating agent like alcohol) converts it into a suspensoid exhibiting the characteristic sensitivity toward electrolytes. The precipitating effect of large amounts of such salts as ammonium sulfate or sodium chloride on emulsoids is due to the fact that saturated solutions of these salts act also as dehydrating agents, thereby discharging and dehydrating the particles at the same time. Fig. 1, from Krulyt, illustrates these differences in stability between emulsoids and suspensoids.

Under changing conditions of temperature and concentrations of disperse phase, hydrogen ions, and electrolytes, emulsoids have the property of imbibing large quantities of water and setting into semirigid gels. These gels are thought to possess a definite structure, consisting in some cases of

a network of disperse phase, or hydrated material, enclosing some of the dispersion medium. On standing for a time most gels gradually contract, extruding a portion of the dispersion medium. This process is known as *syneresis*. The properties of imbibition and gel formation exhibited by emulsoids probably are responsible for the characteristic physical form of protoplasm. The swelling and shrinking exhibited by protoplasm are due probably to the hydration and dehydration of its colloids, presumably governed by the same laws that operate in the case of the simpler systems.

Colloidal particles possess appreciable surfaces which permit such phenomena as surface tension (*q.v.*) to come into play at the interfaces between the particles and the dispersion medium. The magnitude of these surfaces becomes evident when we reflect that if a 1-cm. cube is subdivided into cubes with 10-m $\mu$  edges, the surface area is increased from 6 sq. cm. to 600 sq. m. Substances such as most emulsoid colloids (soaps, proteins, etc.) which decrease surface tension tend to accumulate at surfaces, whereas other substances such as sodium chloride which increase surface tension tend to be less concentrated there. This increase in the concentration of a substance at a surface is known as *adsorption*. In the case of colloidal solutions, adsorption thus involves an increase in concentration in the boundary layer between dispersed phase and dispersion medium. The mechanism of adsorption is obscure; it has been suggested that the adsorbent enters into a loose combination with the material adsorbed by means of latent valences of atoms in the surface layers. In many cases (such as adsorption of many different kinds of gases, liquids, and even solids by such suspensions as charcoal), it is difficult to understand how any kind of chemical combination takes place. When electrolytes are adsorbed by the charged particles in colloidal solutions it is the ion with opposite charge which is adsorbed.

Adsorption probably plays a very important role in many of the reactions taking place in living protoplasm, since in this manner substances ordinarily present in low concentration may have their effective concentrations increased tremendously by being accumulated at boundary surfaces. Concentration by adsorption also finds use in the laboratory in the isolation from very dilute solution of such natural products as enzymes, vitamins, hormones, etc. The adsorbed material may be released (*eluted*) from the surface of the solid adsorbent (e.g., charcoal, metallic hydroxides, fuller's earth) by changing the acidity or surface tension of the solvent. In the process of chromatographic adsorption the solid adsorbent is packed into a tall glass column down which the solution containing adsorbable material is allowed to flow slowly. This procedure is discussed in detail in the section on chromatography (see p. 14).

The studies of Harkins and of Langmuir indicate that substances accumulate at boundary surfaces in a definite pattern. Thus molecules having both polar and nonpolar groups orient themselves at oil-water interfaces in such a fashion that the polar groups dissolve in the water while the nonpolar groups dissolve in the oil. Oleic acid, for example, orients itself at oil-water interfaces so that the polar carboxyl group is directed into the water, which it more closely resembles in general structure than does the nonpolar alkyl group, which is directed into the oil. Since proto-

plasm contains both water and lipide materials it is quite probable that some of the cell constituents are oriented in a similar fashion within the cell. It is also probable that the internal structure of the cell is based upon orientation of various types of molecules within the cell.

## EXPERIMENTS ON COLLOIDAL SOLUTIONS

### A. METHODS FOR PREPARATION OF COLLOIDAL SOLUTIONS

1. *Preparation of Colloidal Solutions of Prussian Blue and of Arsenious Sulfide by Double Decomposition.* To 10 ml. of 0.02 N potassium ferrocyanide in a beaker add with mixing 10 ml. of 0.02 N ferric chloride. Dilute a portion of the mixture and note that there is no precipitate. This colloid is negatively charged.

Mix 50 ml. of 1 per cent arsenious oxide solution (made by boiling the oxide with water) with 50 ml. of saturated solution of hydrogen sulfide. Heat to boiling (in the hood), filter and cool. This colloid is electronegative also.

2. *Preparation of Colloidal Ferric Hydroxide by Hydrolysis.* To 200 ml. of boiling water add 1 ml. of 33 per cent ferric chloride solution, or about 0.3 g. of solid ferric chloride. Note the beautiful reddish-brown color. This is a positively charged colloid.

3. *Preparation of a Gold Sol by Reduction.* To 100 ml. of pure redistilled water add 1 ml. of 1 per cent gold chloride solution and 5 ml. of 0.5 per cent potassium carbonate solution. Heat to boiling, remove from the flame, and add two drops of 20 per cent formaldehyde solution. If necessary, heat again and add one more drop. Observe the changes in color as the particles of metallic gold become larger and larger. Most metallic colloids are electronegative.

4. *Preparation of Colloidal Platinum by Electrical Method.* Connect two short platinum wires (1 to 3 mm. cross-section) with stout copper wires and pass through pieces of glass tubing to serve as handles. Connect both wires with the terminals of a 110-V. d.c. lighting circuit with a lamp bank of five 100-watt lamps in parallel (to cut down the current to about 5 amperes). Place pure distilled water in a crystallizing dish about 4 inches in diameter, add a very slight trace of hydrochloric acid, and immerse the two platinum tips. Bring the tips together and then separate them by about 1 to 2 mm. An arc develops. Maintain this for several minutes. Filter.

5. *Preparation of Emulsoid Solution.* Prepare solutions of gelatin (5 per cent), agar (1 per cent), starch (2 per cent), and soap (2 per cent) by allowing the dry colloid to become thoroughly soaked in the required amount of water in a beaker at room temperature, followed by immersion of the beaker in a boiling water bath, stirring until solution is complete. Cool the solutions and note that gels are formed. Heat again in boiling water and note that the gels liquefy. On standing for some time the gels should show syneresis.

### B. GENERAL PROPERTIES OF COLLOIDAL SOLUTIONS

1. *Diffusion Through Membranes (Dialysis).* Prepare a dialyzing bag from seamless cellulose dialyzer tubing<sup>1</sup> as follows: Cut a strip about 15 cm. long

---

<sup>1</sup> Obtainable from most laboratory supply houses in the form of rolls of varying length and width. If not available, collodion bags may be used. Pour 10 to 20 ml. of collodion solution

from the roll of flat tubing, wet the strip thoroughly with water, and separate the sides to form a tube. (This operation is facilitated by holding the strip vertically in a stream of running water.) Tie one end of the tube tightly with string to form a bag. Fill the bag with colloidal Prussian blue or ferric hydroxide solution (prepared as described above), tie loosely at the top with string, and suspend in a beaker of water. Observe at intervals. Do you detect any diffusion of the colloid through the membrane? Test the water in the beaker for chloride. Is any substance diffusing through the membrane?

**2. Diffusion Through Gels.** Place 5 ml. of 5 per cent gelatin in each of two test tubes. Cool until the gelatin solidifies. Pour copper sulfate over the gel in one tube and Prussian blue solution over the other. Let stand. Note the degree of diffusion of the blue color in the two cases. The experiment may be repeated with eosin and methylene blue, the former a noncolloidal and the latter a colloidal dye.

**3. Mutual Precipitation of Colloids.** Mix equal volumes of solution of the negative colloid arsenious sulfide and the positive colloid ferric hydroxide. Explain. Can you write the equation for any reaction which occurred?

**4. Precipitation of Colloids by Salts.** To a solution of Prussian blue, ferric hydroxide, or other suspensoid, add a few ml. of 10 per cent sodium chloride solution, and allow to stand. Treat a solution of an emulsoid such as gelatin or starch in the same way. Which are precipitated by the electrolyte? Add an excess of water to the precipitate. Is the colloid reversible? If the emulsoid is not precipitated saturate the solution with solid magnesium sulfate. To some of the precipitate add an excess of water and boil. Is the emulsoid reversible?

**5. Demonstration of a Protective Colloid.** To a mixture of three drops of concentrated nitric acid and 5 ml. of 0.05 N silver nitrate add 5 ml. of 0.05 N sodium chloride. Note the curdy precipitate. Repeat, but add 1 ml. of gelatin solution to the silver nitrate and to the sodium chloride solutions before mixing.

**6. Demonstration of Optical Properties of Colloids.** Pass a ray of brilliant light through solutions of typical colloids in beakers. (Colloidal solutions of gold, mastic, ferric hydroxide, or arsenious sulfide give good results.) Note the turbidities where the light strikes the solutions and compare with pure water and ferric chloride solutions, which should contain only traces of dust and other particles. Direct sunlight or arc lamp may be used. The light should be concentrated by means of a lens so that only a part of the solution is illuminated.

If the cone of light be viewed through a Nicol prism and the prism rotated, the field will become alternately light and dark, indicating polarization. Solutions of eosin or quinine fluoresce in the light, but the light is not polarized since these solutions are not colloidal. Also examine a colloidal gold solution under the ultramicroscope and note the Brownian movement of the particles.

---

into a clean dry Erlenmeyer flask or large test tube. Rotate to form a complete film over the inner surface and clamp in an inverted position. After ten minutes loosen the edges of the film with a knife and run water from the faucet between the membrane and the container. Preserve under water until needed.

7. *Viscosity (Internal Friction) of Colloidal Solution.* Fill a 10-ml. pipet with water, suspend it in a vertical position, and allow it to drain. Count the number of seconds required for emptying. Repeat, using a solution of Prussian blue or ferric hydroxide. Repeat again, using a 2 per cent solution of gelatin. How does the viscosity of the suspensoid compare with that of the emulsoid and with that of pure water? A more accurate form of this apparatus is a viscosimeter of the Ostwald type (see Exp. 8). A solution of gelatin shows its lowest viscosity (most rapid emptying of the viscosimeter) at its isoelectric point (about pH 4.7).

8. *Estimation of Viscosity with Ostwald Viscosimeter.* The apparatus illustrated in Fig. 2 is used and is kept in a constant-temperature water bath during the determination. Test with water first. By means of a pipet introduce a suitable exact amount (usually 5 ml.) of water into bulb E. Blow at F and force the liquid above mark C. The fluid column should still reach to bulb E. Allow it to flow back and note the time with a stop watch for the meniscus to pass from C to D. Repeat until constant values are obtained. Repeat with gelatin or some other colloidal solution. If water requires 60 seconds and gelatin solution 120 seconds, the relative viscosity of the gelatin is 2.0.

FIG. 2. OSTWALD VISCOSIMETER.

9. *Adsorption by Charcoal.* Caramelize a small amount of sugar by heating it in a crucible. Dissolve in 100 ml. of water, add 5 g. of animal charcoal, and boil for five minutes. Filter. The filtrate should be colorless. Charcoal is used for clarification in the commercial refining of sugar and in many similar processes. Repeat the experiment, using a dilute solution of crystal violet or other dye instead of the caramelized sugar solution. After the filter has drained, pour alcohol or acetone over the moist charcoal. Does the dye enter into a firm combination with the charcoal? Acetone and alcohol are more strongly adsorbed than crystal violet and tend to displace it from the charcoal. What is this displacement process called?

10. *Electrophoresis of Colloids.* Clamp in an upright position a glass U-tube (one with limbs about 15 cm. long and 2 cm. in diameter is satisfactory). Half fill the tube with a suitable colored colloidal solution (arsenious sulfide, ferric hydroxide). With a pipet slowly and carefully add distilled water to each limb to within about 2 cm. of the top. With suitable care a sharp boundary between the water and the colloidal solution is obtained. Place a platinum electrode in contact with the water in each limb, and connect each electrode to a terminal of known polarity from a source of 110 V. d.c. Note (1) the level of the colloid-water boundary in each limb and (2) the polarity of the electrodes, and turn on the current. Allow it to run until definite movement of the boundary has taken place. What does this experiment prove with regard to the sign of charge on the colloidal particles? Repeat with a colloid of opposite charge.

## DONNAN EQUILIBRIUM

The British physicist Donnan has made a contribution of the utmost importance in physiology to our knowledge of the influence of ions in colloidal systems. Let us suppose a membrane (indicated below by a vertical

line) to be impermeable to the anion R of a salt NaR in solution on one side of the membrane but permeable to all other ions and salts involved. Let us further suppose that we have at the beginning of the experiment NaR on one side of the membrane and NaCl on the other. (See diagram at left, below.) NaCl will diffuse from 2 to 1 until at equilibrium conditions will be as indicated on the right.

Now from thermodynamic considerations it can be calculated, and by actual determination it can be shown, that at equilibrium the product of the concentrations of a pair of diffusible ions (in this case Na<sup>+</sup> and Cl<sup>-</sup>) on one side of the membrane will be the same as the product of the concentrations of the same ions on the other side of the membrane. That is,<sup>2</sup>

$$[\text{Na}^+]_1[\text{Cl}^-]_1 = [\text{Na}^+]_2[\text{Cl}^-]_2$$

The concentration of the cation Na<sup>+</sup> in (1) must be equal to the sum of anions present [R<sup>-</sup> + Cl<sup>-</sup>] in order to maintain electrical neutrality, while on the other side the concentration of Na<sup>+</sup> is the same as that of the anion Cl<sup>-</sup>. It follows that, in order for the products just mentioned to be equal, the concentration of sodium ions [Na<sup>+</sup>] on the left must be greater than on the right and the reverse must be true for the chlorine ions. That is,

$$[\text{Na}^+]_1 > [\text{Na}^+]_2 \quad \text{and} \quad [\text{Cl}^-]_1 < [\text{Cl}^-]_2$$

Thus it is possible to account for the existence of different concentrations of diffusible ions on the two sides of a semipermeable membrane, the essential condition being the existence of a nondiffusible ion on one side of a membrane which is permeable to the other ions.

This difference in concentration of diffusible ions leads to a difference of potential (electrical pressure, measured in volts) on the two sides of the membrane, and may account for certain electrical phenomena of living matter. The Donnan equilibrium has also been associated with the explanation for a variety of physiological phenomena, such as the formation of gastric juice and other secretions, certain aspects of absorption and elimination, and the differences in concentration of diffusible ions between the blood plasma and cerebrospinal fluid and between the red cells and plasma. In this connection it is well to remember that quantitatively the Donnan equilibrium is based upon ion activity rather than concentration, which was used in the above illustration for purposes of simplicity, and it is not always possible to define precisely the relation between these two properties, particularly in physiological fluids.

<sup>2</sup> This may also be expressed by the equation for the Donnan equilibrium  $x^2 = y(y + z)$  where  $x$  is the concentration of Na and Cl ions in the outer solution (2),  $y$  the concentration of Na and Cl ions of the free NaCl in the colloidal solution (1), and  $z$  the concentration of sodium ions in combination with the nondiffusible anion R.  $x$  and  $y$  may be determined and  $z$  then calculated.

## EXPERIMENTS ON DONNAN EQUILIBRIUM

1. *Demonstration of Donnan Equilibrium Using a Membrane.* Introduce 50 ml. of a 2 per cent gelatin solution into one 100-ml. beaker and 50 ml. of distilled water into another. Add 1 ml. of a 0.04 per cent thymol blue solution to each. To the water add 0.1 N hydrochloric acid solution cautiously, drop by drop, until the indicator has a color intermediate between yellow and pink (pH about 2). Add the acid to the gelatin solution until a similar shade of color is obtained (several ml. may be required). The two solutions now have the same hydrogen-ion concentration. Transfer the gelatin solution to a dialyzing bag and suspend it in the beaker containing the water solution. Let it stand. The gelatin solution will gradually turn yellow (decreased acidity) and the outside solution will turn pink (increased acidity), indicating a diffusion of hydrogen ions through the membrane. Do any other ions diffuse? What is the sign of charge on the nondiffusible gelatin ion in this experiment? Explain the results in terms of the Donnan equilibrium.

2. *Demonstration of Donnan Equilibrium without Use of a Membrane.* Prepare 100 ml. of a 5 per cent solution of gelatin. Add 1 ml. of a 0.5 per cent solution of brom thymol blue. Add 0.5 per cent NaOH drop by drop until a color intermediate between yellow and blue (pH about 7) is obtained. Pour it into a 250-ml. beaker and allow it to solidify. Over the gel pour 100 ml. of distilled water containing the same amount of indicator and brought to the same pH. Let it stand, and note the changes in the color of both gel and solution. Explain. Is the presence of an extraneous membrane essential for the development of the Donnan equilibrium?

## CHROMATOGRAPHY

Chromatography is the name originally applied by the Polish botanist Tswett in 1906 to a procedure for separating a mixture of different-colored pigments (chlorophylls and xanthophylls) from each other. Tswett found that if the mixture of pigments in petroleum ether as solvent was poured onto the top of a column of calcium carbonate firmly packed in a narrow glass tube, and allowed to drain down the column, the pigments were separated and appeared as colored zones along the column. By the addition of fresh solvent the zones could be further separated and the separate pigments identified under suitable conditions. Tswett called such a column a *chromatogram* and the process the *chromatographic method*.

As has happened with many other fundamental discoveries, the usefulness of Tswett's simple procedure was not generally appreciated until years later. At the present time chromatographic procedures of one kind or another are probably more widely used in biochemical research than any other single type of procedure. Tswett ascribed the differences in the behavior of pigments placed on his columns to differences in adsorbability, the more strongly adsorbed chlorophylls, for example, displacing the weakly adsorbed xanthophylls and thus forcing the xanthophylls further along the column under the influence of the flowing solvent. There are however instances which are more readily explicable on some other basis. For example, a mixture of amino acids placed on a column of starch or powdered cellulose may be chromatographed and separated by the use of certain solvents, but the order of separation of the various compounds

present parallels their distribution coefficients (see p. 24) between the solvent and water. Since starch or cellulose will take up appreciable amounts of water<sup>3</sup> it is reasonable to assume that the amino acids dissolve in the water of the column and are extracted from it by the flowing solvent in proportion to their relative solubilities in the two phases (*partition chromatography*). In columns containing ion-exchange resins (see below), it is believed that the functional groups of the resin react directly with the various substances placed on the column, but to a different degree. Thus a resin containing acidic functional groups may be expected to react with a mixture of bases placed on the column in the same way that an acid in solution distributes itself between various bases present. In such a column the bases will be distributed along the column, the most reactive base at the top, and upon elution they will emerge from the column at different rates for similar reasons. There are therefore various explanations for the behavior of substances undergoing chromatographic separation, and the science is still far behind the art in this field. Columns satisfactory for particular purposes are ordinarily found by trial; the explanation usually comes later.

Suitable columns have been made from the various insoluble alkaline-earth phosphates and oxides, starch and cellulose, and ion-exchange resins. The dimensions of the column may vary, but in general a column resembles the common volumetric buret in ratio of length to width. Every column has an inherent capacity for the particular substances being fractionated on it; if this capacity is exceeded, separation will be unsatisfactory. If the various substances on the column can be released by solvent change and thorough washing, a used column can be regenerated and used again. The solvent may flow down the column by gravity or more commonly under a controlled pressure head. The rate of flow of solvent may vary; in general, the more slowly the solvent flows, the more thoroughly equilibrium is reached and the potentialities of the column are realized. The solvent may be aqueous or nonaqueous as required, and may be changed during a separation to modify distribution along the column. The wide variety of solvents available is one of the outstanding advantages of chromatography.

The applicability of chromatography is not limited to colored compounds; thus the name is somewhat misleading. Any procedure which identifies a substance may be used to locate it in the column. Fluorescence under ultraviolet light has been used, as has radioactivity, in cases in which the substance under study is labeled with a radioactive isotope. The column may also be extruded from the tube and cut into sections, and each section may be extracted and analyzed for the substance sought. An improved isolation procedure now widely used is based upon the continuous passage of the pure solvent down the column, the effluent solvent being collected in separate fractions and the fractions analyzed for the material under study. The solvent may be varied during this process, to promote the release of particular compounds from the column. Under

---

<sup>3</sup> According to the International Critical Tables, the water content of saturated cellulose is 22 per cent on a dry weight basis.

carefully controlled conditions it is found that a particular compound may show sufficient reproducibility with regard to the fraction of the effluent in which it is found to afford a tentative basis for identification; this procedure has been used by Moore and Stein in their analysis of the amino acids present in protein hydrolyzates.

**Ion-exchange Resins.** The use of ion-exchange resins in chromatography and for other purposes in biochemistry and medicine is of sufficient importance to justify brief consideration at this point. *Ion-exchange resins* are highly insoluble synthetic polymers containing accessible (i.e., titratable) functional groups which are either acidic ( $-\text{COOH}$ ,  $-\text{SO}_3\text{H}$ )

or basic ( $-\text{NH}_2$ ,  $-\text{N}^+(\text{CH}_3)_3$ , etc.). Resins with acidic functional groups, such as Dowex 50, Amberlite IR 100, and Permutit H, are known as *cation-exchange resins*; those with basic functional groups, such as Dowex 1, Amberlite IR 4, and Permutit S, are the *anion-exchange resins*.

The action of resins is best understood by considering them to be polyfunctional acids or bases which happen to be insoluble. Thus if a solution containing an amine salt is placed on a column packed with a cation-exchange resin containing replaceable hydrogen, the resin will take up the amine cation from the solution and replace it in solution by the hydrogen ion (*hydrogen cycle*). The amine may be subsequently displaced from the resin and washed out of the column by the use of a more acid solvent. A mixture of bases on such a column may be released individually by the use of solvents of varying acidity and electrolyte content. In a similar manner, a cation-exchange resin whose hydrogen has been replaced by sodium will function in a sodium cycle toward other cations such as calcium and magnesium. A solution containing a calcium salt will emerge from such a column as a solution of the sodium salt, the calcium remaining attached to the resin. The resin may be returned to its original state by treatment with a large excess of sodium ions. This is a principle used in the softening of hard water. An anion-exchange resin which has been saturated with chloride ion will function in a chloride cycle towards other anions; a column containing such a resin will remove weak organic acids from solution as anions and replace them with chloride.

The use of ion-exchange resins is not confined to chromatography, but is acquiring increasing importance in other aspects of biochemistry and medicine. Examples of such uses include the use of resins to decalcify blood and thus prevent blood clotting; clinical use to control gastric acidity and the dietary absorption of electrolytes from the intestinal tract by the oral administration of suitable resins; and the demineralization of milk for special dietary purposes. Since it is now known that resins can be "tailor made" to fit almost any desired purpose, such clinical use of resins would appear to be on the increase.

**Paper Chromatography.** A remarkable development in the field of chromatography which is perhaps unequalled in the field of biochemical procedures for its simplicity, versatility, and widespread application is the use of filter paper for chromatographic purposes by a procedure first described by Consden, Gordon, and Martin.<sup>4</sup> The basic principle is very

<sup>4</sup> Consden, Gordon, and Martin: *Biochem. J.*, 38, 224 (1944).

simple. A small drop of solution containing the mixture of compounds it is desired to separate is evaporated to dryness on a piece of filter paper, and a suitable solvent is allowed to flow slowly along the filter paper over this spot, either by gravity (descending) or capillarity (ascending). The substances in the initial spot are extracted by the flowing solvent and carried along the filter paper to an extent which is related to their distribution between the solvent and the water phase of the filter paper, as discussed previously. After the solvent has flowed for a suitable distance along the paper, the paper is removed and freed of excess solvent by quickly drying, and suitable tests are applied to the filter paper to locate the various compounds under study. Under the proper conditions it is found that each substance present has been carried away from the initial spot to a characteristic extent and is localized in a relatively small area on the filter paper.

The simplest expression of the response of a particular compound to this procedure is the so-called  $R_F$  value, which is the ratio of the distance the compound moves along the paper to the distance covered by the solvent. Thus if the solvent front is 12.0 cm. from the spot of application of the compound, and the compound is located 9.0 cm. from this spot, the  $R_F$  value is  $9.0/12.0$ , or 0.75. The absolute value of  $R_F$  for a particular compound is of course dependent upon such factors as the nature of the solvent, the temperature, and the presence of other substances which influence the distribution of compound between the solvent and water. With suitable attention to these details, however, the  $R_F$  value for a pure substance is found to be sufficiently reproducible to serve as an approximate basis for identification.

An improved procedure is the so-called two-dimensional chromatography. Here the spot containing the substances under study is dried in one corner of a square of filter paper. The solvent, running as before, carries the substances along one edge of the paper in proportion to their  $R_F$  values for that solvent. After the excess solvent is removed by drying, the paper is turned  $90^\circ$  and a second solvent is allowed to flow across the paper at right angles to the direction of flow of the first solvent and in such a way as to carry the various substances present from the edge of the paper to the middle regions. After the second solvent is removed by drying, the substances are located by suitable means. By the selection of suitable solvents it is possible using this procedure to separate and identify the components of even such complex mixtures as the various amino acids present in a protein hydrolyzate (see Frontispiece), using only small amounts (a few milligrams) of material and ordinary laboratory equipment.

There are of course many refinements to the procedures described here. By the careful use of the technique, the compounds separated are usually localized in a small and reproducible area of the filter paper. If the compound is detected at this spot by a color reaction, measurement of the color intensity may be used to determine the amount of material present. The area may also be cut out and the compound extracted from the paper, thus essentially isolating it in pure solution, for confirmation of its chemical nature by other tests. The student will find many applications of paper chromatography to biochemical problems in this book and in the biochemical literature.

## EXPERIMENTS ON CHROMATOGRAPHY

1. *One-dimensional Paper Chromatography.*<sup>5</sup> For demonstration purposes solutions of amino acids will be chromatographed in this experiment. The amino acids will be located on the filter paper by reaction with ninhydrin to give a purple color. Solutions of glycine, aspartic acid, and a mixture of glycine and aspartic acid, all 0.03 M, will be used. If desired, a fourth solution containing either or both amino acids can be used as an unknown.

Cut strips of Whatman No. 1 filter paper to the dimensions  $13.5 \times 1.8 \times 1.0$  cm. Pierce a small hole in each strip, in the center and about 4 mm. from the broad end. This will be used for hanging the strips during the drying process. To minimize contamination, avoid touching the strips with the fingers.

For each solution under examination, draw a portion into a capillary pipet having a very fine tip,<sup>6</sup> and apply the tip of the pipet quickly and lightly to a filter-paper strip at the center and about 6 mm. from the narrow end. By this procedure a volume of approximately 0.2  $\mu$ l. of solution is deposited on the paper to form an area which should not be in excess of 1.5 mm. in diameter. Circle the wet area with a light pencil line and allow to dry. Prepare a separate strip for each solution under examination.

Place approximately 0.5 ml. of water-saturated phenol<sup>7</sup> in the bottom of a 6-inch test tube. Using one tube for each strip, insert the narrow end of the treated paper strip into the phenol solution in such a way that the strip does not touch the walls of the tube except at the top. Stopper the tube with a soft cork. Allow to stand undisturbed at room temperature for 2 to 3 hours or until the solvent has ascended by capillarity to within about 5 mm. of the hole at the top of the strip. Remove the strip, place a bent wire or paper clip in the hole, and suspend in a drying oven at 110° for about 3 minutes. Remove, and spray the entire strip lightly with a solution of ninhydrin contained in an atomizer.<sup>8</sup> Replace in the oven and dry for about 4 minutes.

With a pencil, mark the edge of the solvent front on the strip, and encircle any colored spots present. Mark the approximate center of each spot. Measure the distance from the original spot where the solution was applied to the edge of the solvent front and to the center of each colored area. Calculate the  $R_F$  value for each colored spot, where  $R_F$  is the ratio of the distance traveled by the material in the spot to the distance traveled by the solvent. How do your values compare with those given by Rockland and Dunn (glycine, 0.49; aspartic acid, 0.25)? From the volume of solution used, and the molar concentration of amino acid, calculate the actual amount of amino acid separated and identified by this procedure.

2. *Two-dimensional Paper Chromatography.* Obtain a sheet of filter paper about 17 cm. square (Whatman No. 1 or Schleicher and Schull No. 597 are satisfactory). Using a capillary micropipet place a small drop of amino acid solution (1–2  $\mu$ l., containing 10–20  $\mu$ g. of amino acid) in one corner of the paper, about 2 cm. from each edge. Circle the wet area with a light pencil line and allow to dry. Roll the paper into a cylinder and staple the edges together.

<sup>5</sup> Procedure of Rockland and Dunn: *Science*, **109**, 539 (1949).

<sup>6</sup> Draw 5-mm. pyrex capillary tubing to about 2 mm., cut into suitable sizes, and grind the tip to about 0.5 mm. with 400–600 mesh carborundum. These pipets deliver about 0.2  $\mu$ l. when used as described. Micropipets may be obtained from Microchemical Specialties Co., 1934 University Ave., Berkeley, California.

<sup>7</sup> Add 25 ml. of distilled water to 75 g. of pure phenol. Warm to bring about solution. A pink color is not objectionable.

<sup>8</sup> Dissolve 0.25 g. of ninhydrin in 100 ml. of water-saturated butanol.

Do not overlap the edges, but allow the staples to serve as links. Stand the cylinder upright, with the applied spot at the bottom, in a 10-cm. petri dish filled to a depth of about 0.5 cm. with a suitable solvent (see below). Cover the assembly with a bell jar or battery jar, preferably with a tightly fitting glass plate as a base. Allow to stand until the solvent has risen to within a few centimeters of the top of the cylinder. Remove from the petri dish, dry quickly in an oven, and unroll. Remove the staples, turn the paper so that the circled spot is in the lower right corner, and make a new cylinder as before. Place upright in a petri dish containing a second solvent, cover with a bell jar, and let stand as before. When the solvent has risen to within a few centimeters of the top of the paper, remove from the petri dish and dry quickly in an oven. Unroll, spray the dried paper uniformly with ninhydrin solution, and dry as described under Exp. 1. Circle the colored areas with a pencil line to mark the spots, since the colors will fade in a few days.

Try this experiment with solutions of various amino acids and with various solvents. Suitable solvents<sup>9</sup> include (1) water-saturated phenol (Exp. 1); (2) a mixture of 70 parts *n*-propanol and 30 parts water; (3) a mixture of equal parts of 2,4,6-collidine, and 2,4-lutidine to which one-third volume of water is added; (4) a mixture of *tert*.-butanol, water and 85% formic acid in the proportions of 69.5:29.5:1.0; (5) water-saturated phenol made alkaline with 1% concentrated  $\text{NH}_4\text{OH}$ . How do your results compare with those shown in the frontispiece?

**3. Detection of Glutamate in Canned Foods.** An interesting use of the procedure described in Exp. 1 has been described by Patton and Foreman<sup>10</sup> for the detection of added sodium glutamate in processed foods. Sodium glutamate is an approved flavoring agent which may or may not be added to canned foods such as chicken soup. Try the procedure of Exp. 1, using fluid from commercial canned chicken soup or meat sauce. As a control, run an 0.03 M solution of sodium glutamate. As a second control, glutamate may be added directly to the solution under test. Do your results indicate the presence of glutamate in the food tested?

**4. Column Chromatography.** Experiments illustrating the use of column chromatography will be found in Chapters 7 and 10.

## OSMOTIC PRESSURE

Membranes which permit the passage of molecules of the solvent but not of the molecules or ions of a substance in true solution are known as *semipermeable membranes*. One type of semipermeable membrane is made by depositing copper ferrocyanide in the walls of a porous porcelain cup. If such a cup is filled with a solution of sugar in water and is then immersed in water, the sugar molecules cannot pass through the membrane. The water molecules, however, permeate readily and the level of the solution in the cup will rise. The pressure that must be exerted upon the solution within the cup to prevent any increase in volume is a measure of the osmotic pressure of the solution. The magnitude of osmotic pressure is indicated by the fact that a 10 per cent solution of cane sugar at 25° C. has an osmotic pressure of 7.6 atmospheres.

Whatever may be the fundamental cause of osmotic pressure there is no

<sup>9</sup> Underwood and Rockland: *Food Res.*, **18**, 17 (1953).

<sup>10</sup> Patton and Foreman: *Food Tech.*, **4**, 83 (1950).

question but that it appears to be, for substances in solution, analogous to the pressure of gaseous molecules. Thus 1 gram-molecular weight of an ideal gas at 0° C. and in a volume of 1 liter exerts a pressure of 22.4 atmospheres; 1 gram-molecular weight of an ideal nonelectrolyte in solution under the same conditions has an osmotic pressure of 22.4 atmospheres. Furthermore under ideal conditions osmotic pressure is, like gas pressure, directly proportional to the absolute temperature and to concentration, and is independent of the chemical nature of the dissolved material. Thus equimolecular concentrations of all nonelectrolytes have the same osmotic pressure, or are isosmotic. It is therefore possible to determine molecular weight by the measurement of osmotic pressure, and this procedure has found considerable application in biology.

The osmotic pressure of electrolytes is considerably higher than that of equimolar solutions of nonelectrolytes, since an ion is theoretically as effective osmotically as a molecule. For example, a solution of NaCl containing  $\text{Na}^+$  and  $\text{Cl}^-$  ions should have twice the osmotic pressure of an equimolar solution of nonelectrolytes such as glucose or urea. By actual measurement it is usually found that the osmotic pressure of electrolytes is somewhat less than the expected value, presumably because of differences between the osmotic effectiveness (*activity*) of the ions and their concentration. The relation between ion concentration and activity must be considered in any calculation of osmotic pressure for solutions containing electrolytes.

A colloidal particle is as effective osmotically as a molecule or ion. Colloidal solutions therefore have very low osmotic pressures compared to equal weights of substances in true solution because of the large size and relatively small number of particles present. Colloidal osmotic pressures, although small, are nevertheless very important in biology, since colloids do not ordinarily diffuse through membranes and only substances which are impermeable to a membrane ordinarily can influence the osmotic flow of fluid across the membrane. For example, the osmotic pressure of the blood colloids is only about 0.5 of 1 per cent of the total osmotic pressure of blood, yet the blood colloids become the determining factor in the flow of fluid by osmosis across those physiological membranes which are freely permeable to all other dissolved substances present.

The maintenance of the normal water content of plant and animal cells is determined largely by osmotic pressure relationships. Cells placed in contact with a medium which has a lower osmotic pressure than the cell contents will absorb water (swell), the extent of swelling depending upon the osmotic-pressure difference between cell contents and medium. Such a medium is said to be hypotonic to the cell. A hypertonic solution will bring about the reverse process, the cell losing water and diffusible solutes to the medium, and shrinking. If the medium causes no change in cell volume, it is isotonic to the cell. In relating these phenomena to the osmotic pressures of the cell contents and of the surrounding medium, for reasons given above it is essential that permeability of the cell membrane to the solutes present be taken into consideration.

Osmotic pressure may be measured by the use of a semipermeable membrane as described previously and illustrated by the experiments which

follow; but for practical reasons associated with the enormous pressures concerned and the difficulty in obtaining a truly semipermeable membrane, other methods are usually employed for all except colloidal solutions. These methods make use of those other physical properties of solutions which, like osmotic pressure, depend upon the number of dissolved particles (e.g., vapor pressure, rise in boiling point, or depression of freezing point of the solvent). An aqueous solution with an osmotic pressure of 22.4 atmospheres, for example, has a freezing point  $1.86^{\circ}\text{C}$ . below that of pure water, with other values in direct proportion. The freezing-point method is by far the most widely used in investigations on osmotic pressure in biological fluids.

## EXPERIMENTS ON OSMOTIC PRESSURE

**1. *Demonstration of Osmotic Pressure of a True Solution (Cane Sugar).*** Prepare a dialyzing bag similar to that described on p. 10. Tie the mouth of the bag to a one-hole rubber stopper. With a pipet fill the bag with a 10 per cent solution of cane sugar. Insert a glass tube (about 30 cm. long and of 1 to 2 mm. bore) through the hole in the stopper until the end dips below the surface of the fluid in the bag. Blow gently through the tube to create a slight positive pressure in the bag. Support the bag in a large beaker of water with the glass tube in an upright position and the level of fluid in the bag and beaker approximately the same. Observe the rise of fluid in the glass tube. Ultimately the sugar will diffuse through the membrane and the solution level in the tube will fall, but meanwhile the existence of an osmotic pressure will be demonstrated. Copper ferrocyanide membranes deposited in porcelain cups are truly semipermeable, and are necessary for quantitative determination of the osmotic pressure of true solutions by this method.

**2. *Demonstration of Osmotic Pressure of Colloidal Solutions.*** The bag employed in Exp. 1, or a similar one, may be used and the determination is made in the same way. The highest point of the column is generally reached in five or six hours. Membranes of this type are not permeable to proteins, so a true measure of their osmotic pressure may be obtained. The pressures attained, however, are very much lower. A 1 per cent solution of gelatin may give a rise of 25 to 50 mm.

**3. *Osmotic Pressure of Red Blood Cells.*** Add a drop or two of blood to 5 ml. of each of the following solutions: 0.3, 0.9, and 5.0 per cent sodium chloride. Examine each suspension under the microscope. Explain the findings. Calculate the molar concentration and approximate osmotic pressure of each of the three solutions. What is the osmotic pressure of the red-cell contents?

Repeat, using the following solutions: 0.16 M sodium chloride, 0.32 M urea, and 0.32 M urea containing 0.16 M sodium chloride. Observe as above. Calculate the osmotic pressure of these solutions. Which are isosmotic with the red cell? Which are isotonic? Explain.

## SURFACE TENSION

The molecules in the interior of a liquid are surrounded by other molecules on every side and are thus subject to uniform attractions in every direction. On the other hand the molecules in the surface are attracted inward and by other molecules in the surface, but there is little attraction outward because there are so few molecules outside. The result of this

inward attraction is that the number of molecules in the surface tends to be reduced to a minimum and the surface contracts until its area is the smallest possible for a given volume of liquid. This explains the tendency of small drops of liquid to assume a spherical form. This spontaneous contraction of a liquid surface indicates that there is a certain free energy in the surface, and that in order to extend this surface by bringing molecules into the surface a certain amount of work must be done in overcoming the attraction of the other molecules in the interior. It is customary, in considerations involving surface forces, to substitute for the free surface energy the concept of a surface tension acting in all directions parallel to the surface. Thus, if the surface tension of a liquid is  $\gamma$  dynes per cm., the work done in increasing the surface area by 1 sq. cm. will be  $\gamma$  ergs, and the free surface energy of the surface will be  $\gamma$  ergs per sq. cm.

When two immiscible liquids are in contact with each other, the dividing surface or interface also contracts spontaneously because each type of molecule in the surface is attracted by its own kind of molecule in the interior. Thus the interface also possesses a free surface energy, or a surface tension known as the interfacial tension. When the interfacial tension between two liquids is zero, the two liquids are completely miscible.

An intimate mixture of two immiscible liquids is known as an *emulsion*, one liquid being dispersed in the form of droplets in a continuous or external phase of the other liquid. Emulsification is facilitated by the presence of substances called emulsifying agents, which minimize the tendency of the droplets to coalesce. Among the most effective of such agents are substances which lower surface tension, such as soaps, proteins, bile salts, etc. The action of bile salts in lowering surface tension is an important aid in the emulsification and digestion of fats in the intestinal tract.

Emulsions may be of either the oil-in-water or the water-in-oil type, depending upon which liquid is the continuous phase. Sodium soaps, which are more soluble in water than in oil, promote the formation of oil-in-water emulsions; calcium or magnesium soaps, which are oil-soluble, promote the formation of water-in-oil emulsions. This has been offered as an explanation for certain antagonistic effects of  $\text{Na}^+$  and  $\text{Ca}^{++}$  ions on the physical state of protoplasm.

## EXPERIMENTS ON SURFACE TENSION

**1. Demonstration of Surface Tension.** Half fill a large thoroughly cleaned and washed beaker with fresh distilled water. Sprinkle some small particles of camphor over the surface. The particles will move about rapidly on the surface. (Camphor lowers the surface tension of water.) The tension of the surface film will be lowered more rapidly on one side of the particle than on another because of more rapid solution of the camphor at some points, and the particle will be pulled in the direction of greater tension. Touch a glass rod to a cake of soap and then to the surface of the water. The surface tension is greatly reduced and the particles instantly stop moving. Rinse the beaker thoroughly and repeat, but touch the glass rod to the oily skin of the face and then to the water surface. (Oil also reduces surface tension.) The particles will move away from the rod (point of low tension) and will finally stop moving. It has been calculated that a layer of oil one molecule deep is sufficient to produce this effect.

**2. Determination of Relative Surface Tension by Drop Method.** The surface of a liquid tends to contract so as to produce a minimum area. When flowing through a small opening it therefore tends to form drops which fall away when gravity overcomes the surface tension. The number of drops formed from a given weight or volume of fluid varies, therefore, with the surface tension.

**Procedure.** Set up a Traube stalagmometer as in Fig. 3 so that the whole may be immersed in a constant-temperature bath. For approximate comparative results an ordinary 1- or 2-ml. pipet clamped in a vertical position may be used, regulating the out-flow by the use of the finger or a piece of rubber tubing with attached screw clamp so that discrete drops are formed at a uniform rate. Fill it with water above mark A. When the level of the water falls to this mark, start counting the number of drops that fall until mark B is reached. By means of the scale divisions above and below A and B (knowing how many divisions correspond to a drop), fractions of a drop may be estimated. If  $\gamma$  represents the relative surface tension of the liquid tested,  $N_W$  the number of drops of water,  $N$  the number of drops of the unknown, and  $S$  its specific gravity,  $\gamma = \frac{N_W \cdot S}{N}$ .

Determine the surface tensions of water, of a very dilute soap solution, and of olive oil, cleaning the instrument thoroughly between tests, and rinsing several times with the solution tested before taking readings. Olive oil has a lower surface tension than water. Soaps markedly lower the surface tension of aqueous solutions.

**3. Determination of Surface Tension by Ring Method of Du Noüy.**<sup>11</sup> The drop method for determining surface tension described in Exp. 2 is a static method.

So also is the measurement of the rise of fluid in a capillary tube. The oscillating-jet method is a dynamic method in that new surfaces are constantly being formed. All methods give practically concordant results in the case of pure liquids, but not in the case of solutions.<sup>12</sup> Du Noüy has suggested a static method based on the measurement of the force required to overcome the adherence of a platinum ring to the surface of the liquid in question. The apparatus consists of a platinum ring hanging from a lever arm which can be raised by applying torsion to the wire to which it is fixed. The torsion is measured on a scale which can be calibrated directly in dynes per cm., the absolute unit of surface tension. Determinations of surface tension by this method may be accurately made on 1-ml. portions of fluid in 20 to 30 seconds. The method is particularly useful in physiological studies.<sup>13</sup> The surface ten-

## DISTRIBUTION OF DISSOLVED SUBSTANCES BETWEEN LIQUID PHASES

If a substance is soluble in each of two liquids which are immiscible and in contact with each other, it is found that at equilibrium the substance is distributed between the two liquid phases in a characteristic manner. The numerical expression of this property is the *distribution coefficient* (sometimes called *partition coefficient*)  $K$ , which is defined as the ratio at equilibrium of the concentration  $C_A$  of substance in phase  $A$  to its concentration  $C_B$  in phase  $B$ , i.e.  $K = C_A/C_B$ . It is clear that  $K$  is characteristic for a particular set of conditions only, since its value will be influenced by any factor affecting solubility in either phase, such as temperature, pressure, the presence of other solutes, the effect of various solvents on association or dissociation of solute, etc.

The distribution of biologically important substances between "water"

<sup>14</sup> Du Noüy: *J. Exptl. Med.*, 41, 779 (1925).

<sup>15</sup> Du Noüy: *J. Gen. Physiol.*, 7, 625 (1925).

and "oil" phases of protoplasm has attracted considerable attention. It is not surprising to find that substances which are predominantly lipide-soluble are concentrated in the various fats and oils of living tissues. The presence of fat-soluble vitamins in various fish-liver oils is an example, as is also the reported concentration of the insecticide DDT in the fat of milk obtained from cows exposed to DDT-contaminated areas. The action of drugs has been studied in relation to water-lipide distribution. According to one theory, the relative lipide-solubility of various drugs is of importance in determining penetrability of such drugs into, and action upon, such tissues as the brain and nerves, which are relatively rich in lipide material. In connection with such theories however it must be remembered that the physical nature of the so-called *oil phase* of protoplasm has not been too clearly defined. There are relatively few tissues other than adipose and similar tissue where discrete fat droplets are found within the cell. The lipide material of brain and nerve tissue is not fat or oil but consists of phospholipides and similar compounds (see p. 290) which are dispersed within the primarily aqueous phase of the cell in a way which is not entirely clear, but is known to involve intimate association with the proteins and other water-soluble constituents of the cell. The extent to which the distribution of a drug or other substance between water and peanut or olive oil, as determined in the laboratory, is applicable to the complex environment of the living cell remains to be more clearly defined.

The distribution of dissolved material between immiscible solvents has many practical applications. Widespread use is made of such nonaqueous solvents as ether, chloroform, and benzene for the extraction from biological material of lipides, fat-soluble vitamins, various organic acids, and other similar substances. An important advance in the use of solvent distribution for the isolation and characterization of substances of biological importance has been made by Craig<sup>16</sup> in devising his procedure for *counter-current distribution*. In this procedure the material under examination is subjected to a unique and systematic series of extractions by an immiscible solvent in a sequence of extraction vessels or tubes in such a way that various substances become separated and distributed among the tubes in a characteristic manner. The region of concentration of a particular substance among the extraction tubes (the *zone* or *band*) is determined largely by the distribution coefficient of the substance between the two phases used, and the number of extractions applied. In the theoretical treatment of countercurrent distribution, the localization of material has been compared to the effect of the various plates in a fractional distillation column. As in such a column, even closely related compounds may be separated from one another by countercurrent distribution. The curve relating the amount of material present to the number of extractions has a characteristic location for a particular substance and may be used for identification purposes. Furthermore, the shape of the curve is predictable on a theoretical basis for a homogeneous substance; any deviation from such a theoretical curve may be construed as indicating the presence

---

<sup>16</sup> Craig: *J. Biol. Chem.*, **155**, 519 (1944); *Anal. Chem.*, **22**, 1346 (1950).

of impurities. Countercurrent distribution has found wide application in the isolation and characterization of biologically active substances, comparison of natural and synthetic compounds, and establishment of the purity of drugs and similar substances. An experiment illustrating the principles involved is described below.

## EXPERIMENTS ON DISTRIBUTION OF DISSOLVED SUBSTANCES BETWEEN LIQUID PHASES

**Countercurrent Distribution.** 1. This experiment is designed to illustrate the principles of Craig's countercurrent-distribution procedure for the isolation and identification of substances in solution. A study will be made of the distribution of propionic acid between 2.2 M phosphate buffer at pH 5.2 (aqueous phase) and isopropyl ether.<sup>17</sup>

Set up nine 25-ml. graduated cylinders with tightly fitting glass stoppers, and number them from 0 to 8. Place 15 ml. of water-saturated isopropyl ether<sup>18</sup> into each tube. Into Tube 0 place 0.2 ml. of propionic acid. Now add 7.5 ml. of phosphate buffer to Tube 0, stopper, and invert 50 times. Allow the layers to separate. Remove the lower layer as completely as possible<sup>19</sup> and transfer it to Tube 1. Add 7.5 ml. of fresh lower phase to Tube 0. Stopper, equilibrate by inverting both tubes 50 times as before, and allow the phases to separate. Transfer the lower phase of Tube 1 to Tube 2, the lower phase of Tube 0 to Tube 1, and add 7.5 ml. of fresh lower phase to Tube 0. Again invert all tubes 50 times. Continue the transfer of lower phase from each tube to the succeeding tube, the addition of fresh lower phase to Tube 0, and the equilibration, until all nine tubes have equal volumes of both phases. The distribution is now completed within the limits of the number of tubes used.

During this experiment, the volumes of the two phases should be noted occasionally, particularly that of the leading lower phase, and any deficit made up by the addition of fresh lower or upper phase as required, so that the ratio of phases is maintained at 2:1 in each tube. To facilitate equilibration between transfers, it is convenient to clamp the cylinders or tubes to a horizontal rod which can be turned with a crank. Such a device is illustrated in Fig. 5. In place of the glass cylinders, test tubes or separatory funnels may be used.

When the distribution is completed, transfer a 2-ml. portion of each upper phase to separate Erlenmeyer flasks, add 10 ml. of 95 per cent alcohol and 5

---

<sup>17</sup> For the use of this system in the separation of various lower fatty acids, see Sato, Barry and Craig: *J. Biol. Chem.*, 170, 501 (1947).

<sup>18</sup> Solutions required.

*Isopropyl ether, c.p.*

*Phosphate buffer, 2.2 M, pH 5.2.* Dissolve 132 g. of  $\text{KH}_2\text{PO}_4$  and 46 g. of  $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$  in about 400 ml. of warm distilled water, cool, dilute to 500 ml. in a volumetric flask, and mix.

Before use, both the isopropyl ether and the phosphate buffer must be saturated with each other. It is convenient to place the 500 ml. of phosphate buffer into a 1-liter glass-stoppered bottle and then fill the bottle with isopropyl ether. Shake well and allow the phases to separate. As needed, the isopropyl ether may be drawn from the upper phase and the phosphate buffer from the lower phase. Occasional shaking will keep the two phases saturated at room temperature.

*Phenolphthalein solution.* See Appendix.

*Sodium hydroxide, 0.01 N.* Dilute 10 ml. of 0.1 N sodium hydroxide solution to 100 ml. with water in a volumetric flask, and mix.

<sup>19</sup> A hypodermic syringe with a long needle or a pipet with a fine tip, attached to a hypodermic syringe by rubber tubing, are satisfactory. The same syringe or pipet may be used for all transfers, and it is not necessary to rinse between transfers.

drops of 1 per cent alcoholic phenolphthalein solution to each flask, and titrate with 0.01 N NaOH solution to the first permanent pink color. As a control, titrate 2 ml. of fresh upper phase in the same way. Subtract the buret reading for the control from that for each tube. Plot milliliters of alkali required for each tube against tube number, on cross-section paper, and draw

FIG. 5. COUNTERCURRENT DISTRIBUTION INVOLVING 12 TRANSFERS.

a smooth curve to include all the points. This is the distribution curve for the particular solute and solvent pair used.

CALCULATION. The approximate value of the distribution coefficient  $K$  may be calculated from the formula:<sup>20</sup>

$$N = n \times \frac{1}{1 + rK}$$

where  $N$  is the tube number at the peak of the curve,  $n$  is the number of transfers, i.e. the number of tubes minus 1 (in this experiment equal to 8) and  $r$  is the ratio of

<sup>20</sup> This equation is derived from the original equation  $N = n \times \frac{K}{K + 1}$  which was developed for movement of the upper phase, with equal volumes of the two phases present. When the lower phase moves, and the ratio  $r$  of upper-phase volume to lower-phase volume is other than 1.0,  $K$  in the original equation is replaced by  $1/Kr$ , and the equation in the text is obtained. For a discussion of the limitations of these equations, see Williamson and Craig: *J. Biol. Chem.*, 168, 687 (1947).

upper-phase volume to lower-phase volume, i.e.,  $r = 2.0$ . How does your value compare with the value of 0.50 estimated by Sato *et al.*?

Another method for calculating the value of  $K$  is based on the fact that the ratio of the concentrations of substance analyzed for in any two tubes is related to  $K$  as follows:

$$K = \frac{1}{F} \times \frac{T_N}{T_{N-1}}$$

where  $T_N$  and  $T_{N-1}$  refer to the amounts of material (or aliquots thereof, since ratios are concerned) found in tube  $N$  and in the tube immediately preceding it in the countercurrent distribution.  $F$  is a factor, differing for each tube,<sup>21</sup> with the following values in this experiment:  $N = 2$ ,  $F = 7/2$ ;  $N = 3$ ,  $F = 6/3$ ;  $N = 4$ ,  $F = 5/4$ ;  $N = 5$ ,  $F = 4/5$ ;  $N = 6$ ,  $F = 3/6$ . Again replacing  $K$  by  $1/Kr$  for reasons already given,<sup>20</sup> the equation as applied here is:

$$K = \frac{1}{r} \times F \times \frac{T_{N-1}}{T_N}$$

Using this equation, calculate  $K$  when  $N$  equals 2, 3, 4, 5, and 6. Average your results. How do they compare with the value obtained above?

2. Repeat this experiment using (a) acetic acid ( $K = 0.09$ ) and (b) butyric acid ( $K = 2.24$ ). How do the curves and calculated results compare with those for propionic acid?

## HYDROGEN-ION CONCENTRATION

**Acids and Bases: Hydrogen-ion Concentration and Titratable Acidity.** Acids may be defined as compounds which yield positively charged hydrogen ions<sup>22</sup> in solution; bases, as compounds which yield negatively charged hydroxyl ions in solution. Strong acids, such as HCl, are completely ionized at all concentrations; they therefore have a hydrogen-ion concentration which is equal to the concentration of acid present. Weak acids, such as acetic acid, exist in solution largely in the molecular or undissociated form, and have a hydrogen-ion concentration under ordinary conditions which is small relative to the total acid concentration. A similar distinction is made between strong bases and weak bases. Most neutral salts are considered to be completely ionized in solution.

When acids react with bases a double decomposition occurs which results in the formation of a salt and water, as in the following equation.

<sup>21</sup> For the derivation and significance of this factor, see Williamson and Craig, *loc. cit.*

<sup>22</sup> According to modern concepts of atomic structure the hydrogen ion is a hydrogen atom which has lost an electron, leaving a proton, with the symbol  $\text{H}^+$ . Until relatively recently this symbol was commonly accepted to signify the *hydrogen ion in aqueous solution*. There is considerable evidence, however, that the proton and the hydrogen ion are not identical, and that the hydrogen ion is a proton which has reacted with water to form an ion such as  $\text{H}_3\text{O}^+$ . For purposes of simplicity the symbol  $\text{H}^+$  will continue to be used throughout this book to signify the hydrogen ion, since the theoretical treatment as presented is independent of the symbol used.

Such reactions, known as neutralization reactions, go to completion because the water formed during the reaction is itself so feebly ionized that its formation leads to the removal of practically all of the hydrogen and hydroxyl ions from solution. The amount of base required to neutralize a definite volume of acid (i.e., the titratable acidity) depends entirely upon the concentration of the acid and is independent of its degree of dissociation. This fact becomes evident upon study of the above equation. As the base is added some of the hydrogen ions in the solution combine with the added hydroxyl ions to form water, and are thus removed from solution. This removal of hydrogen ions disturbs the equilibrium between the undissociated molecules of acid and its ions, and more of the acid dissociates in an attempt to restore this equilibrium. If sufficient base is added this process will continue until all of the acid has been dissociated and neutralized. This will be the case irrespective of whether the acid was originally highly ionized or feebly ionized—i.e., whether it was a strong acid or a weak acid. On the other hand, the hydrogen-ion concentration of an acid—i.e., the actual amount of free hydrogen ions present in the solution at a particular time—depends not only upon the concentration of the acid but also, for weak acids, upon the degree of dissociation. Thus the hydrogen-ion concentration of normal hydrochloric acid, which is 100 per cent ionized, is approximately 100 times as great as the hydrogen-ion concentration of normal acetic acid, in which less than 1 per cent of the molecules are dissociated. As indicated above, however, equal volumes of normal hydrochloric and normal acetic acids will be neutralized by exactly the same amounts of base. In other words the titratable acidities of these acids, or the amounts of hydrogen ions which they are capable of yielding on complete dissociation, are the same. The preceding discussion of the hydrogen-ion concentrations and titratable acidities of weak and strong acids applies just as well to the hydroxyl-ion concentrations and the titratable alkalinities of weak and strong bases.

**Chemical Equilibrium: Ionization Constants.** According to the law of mass action a reversible reaction of the type

proceeds from left to right at a velocity ( $v_1$ ) which is proportional to the product of the concentrations of  $A$  and  $B$ —i.e.,  $v_1 = k_1 [A] [B]$ . Similarly, the opposite reaction takes place at a rate ( $v_2$ ) proportional to the product of the concentrations of  $C$  and  $D$ —i.e.,  $v_2 = k_2 [C] [D]$ . At equilibrium the velocities in opposing directions are equal, and hence  $k_1 [A] [B] = k_2 [C] [D]$

or  $\frac{[C] [D]}{[A] [B]} = \frac{k_1}{k_2} = K$ . This expression of the law of mass action states that for a reversible reaction the ratio of the product of the concentrations of the reacting substances on one side of the equation to that of the product of the concentrations of the substances on the other side is constant. That is,

$$\frac{[C] [D]}{[A] [B]} = K$$

Applying this to weak acids, HA, which ionize according to the equation,  $\text{HA} \rightleftharpoons \text{H}^+ + \text{A}^-$ , we find that at equilibrium

$$\frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]} = K_A$$

In this case the equilibrium constant, since it measures the equilibrium between the undissociated molecules of acid and its ions, is known as the dissociation constant,  $K_A$ . For weak bases, similarly, the dissociation constant of the base BOH is given by

$$\frac{[\text{B}^+][\text{OH}^-]}{[\text{BOH}]} = K_B$$

From the above equations it is readily seen that the larger the numerical value of the dissociation constants, the more completely the acid or base is dissociated—i.e., the stronger the acid or base.

An acid solution is one that contains an excess of hydrogen ions. An alkaline solution is one that contains an excess of hydroxyl ions. A neutral solution is one that contains hydrogen and hydroxyl ions in equal concentrations. Pure water is a neutral solution. It is dissociated to an extremely small extent according to the equation

Applying the law of mass action to this dissociation we get

$$\frac{[\text{H}^+][\text{OH}^-]}{[\text{H}_2\text{O}]} = K$$

Since the concentrations of  $\text{H}^+$  and  $\text{OH}^-$  in pure water or in dilute aqueous solutions are so small compared with the concentration of undissociated water molecules, the concentration of the latter,  $[\text{H}_2\text{O}]$ , may be considered as constant, and the equation then becomes  $[\text{H}^+] \times [\text{OH}^-] = K [\text{H}_2\text{O}] = K_w$ . In other words, the *product* of the concentrations of the H and OH ions is constant. The value of  $K_w$  at  $25^\circ \text{C}$ . has been found to be  $1 \times 10^{-14}$ . That is,  $[\text{H}^+] \times [\text{OH}^-] = 1 \times 10^{-14}$ . In pure water, for every hydrogen ion set free a hydroxyl ion must also be liberated so that the concentrations of the two ions remain equal—that is,  $[\text{H}^+] = [\text{OH}^-]$ . Therefore,  $[\text{H}^+] \times [\text{OH}^-] = [\text{H}^+]^2 = [\text{OH}^-]^2 = 1 \times 10^{-14}$ . Then  $[\text{H}^+] = [\text{OH}^-] = \sqrt{1 \times 10^{-14}} = 1 \times 10^{-7}$ . Thus pure water or a neutral solution contains approximately  $1 \times 10^{-7}$  moles<sup>22a</sup> of H or OH ions per liter and is a 1/10,000,000 normal solution of H or OH ions.

Hydrogen-ion concentrations are now generally expressed, for practical as well as theoretical reasons, as their logarithms with the sign reversed and indicated by the term pH. Thus<sup>23</sup>  $\text{pH} = -\log [\text{H}^+]$ ; or  $[\text{H}^+] = 10^{-\text{pH}}$ .

<sup>22a</sup> A mole (or gram ion) of hydrogen is 1 g.; of hydroxyl,  $16 + 1 = 17$  g.

<sup>23</sup> This definition will be used throughout this book, even though it is not quite exact. For example, HCl in 0.1 N solution is completely ionized, so the solution must have a hydrogen-ion concentration of 0.1 N, or  $1 \times 10^{-1}$  moles per liter (pH 1.00). The value determined experimentally by the use of the hydrogen electrode is 83 per cent of this, or  $0.83 \times 10^{-1}$  moles per liter (pH 1.08). Thus if 0.1 N HCl has a pH of 1.08 (a generally accepted value), the pH does not correspond exactly to the negative logarithm of the hydrogen-ion concentration known to be present. This discrepancy becomes less with more dilute solutions.

The logarithm of  $1 \times 10^{-7}$  is  $-7.0$  and the pH is  $7.0$ . To take another example, the hydrogen-ion concentration of  $0.1 \text{ N HCl}$  is  $8.3 \times 10^{-2}$ . The logarithm of the product of two numbers is equal to the sum of their respective logarithms. In this case, then,  $\log (8.3 \times 10^{-2}) = \log 8.3 + \log 10^{-2}$  (consulting table of logarithms<sup>24</sup>)  $= 0.92 + (-2) = -1.08$ . The pH, being the negative log of the hydrogen-ion concentration, equals  $-(-1.08)$  or  $1.08$ . To convert pH values to hydrogen-ion concentrations the procedure is reversed—e.g., in the case of pH  $1.08$ , the  $[\text{H}^+] = 10^{-1.08} = 10^{-2+0.92} = 10^{-2} \times 10^{0.92}$ . The logarithm of a number is the power to which 10 must be raised to give the number, hence the value of  $10^{0.92}$  is obtained by looking up the number whose logarithm is  $0.92$  (i.e., antilog  $0.92$ ). This is found to be  $8.3$ . pH  $1.08$  is therefore equal to a  $[\text{H}^+]$  of  $8.3 \times 10^{-2}$ .

Since the product of the H and OH ion concentrations is constant at  $1 \times 10^{-14}$ , when the  $[\text{H}^+]$  increases from  $1 \times 10^{-7}$  (pH  $7.0$ ) to  $1 \times 10^{-4}$  (pH  $4.0$ ) the  $[\text{OH}^-]$  decreases to  $1 \times 10^{-10}$  (pOH  $10.0$ ). The sum pH + pOH always equals  $14$ . According to this nomenclature an *increase* in pH indicates a *decrease* in hydrogen-ion concentration or true acidity.

Since the hydrogen-ion concentration varies in a definite reciprocal manner with hydroxyl-ion concentration, the pH scale is universally used to express degrees of alkalinity as well as of acidity, as indicated in the second column below.

| Normality of $[\text{H}^+]$ | pH |            | pOH | Normality of $[\text{OH}^-]$ |
|-----------------------------|----|------------|-----|------------------------------|
| N/10                        | 1  | Acidity    | 13  |                              |
| N/1,000                     | 3  |            | 11  |                              |
| N/1,000,000                 | 6  |            | 8   |                              |
| N/10,000,000                | 7  | Neutrality | 7   | N/10,000,000                 |
|                             | 8  | Alkalinity | 6   | N/1,000,000                  |
|                             | 11 |            | 3   | N/1,000                      |
|                             | 13 |            | 1   | N/10                         |

**Buffer Action and Buffers.** By buffer action is meant the ability of a solution to resist marked change in pH on the addition or loss of acid or base. Substances whose presence in the solution are responsible for buffer action are known as buffers. Though strong acids or bases may sometimes act as buffers, under ordinary conditions the most common basis for buffer action lies in the presence within the solution of a weak acid (or weak base) together with its salt. Such solutions have characteristic properties with respect to hydrogen-ion concentration which are of value not only in the laboratory but also in the living organism, and an understanding of these properties is of fundamental importance.

If we take for example a solution containing a weak acid, HA, and its salt, BA, the hydrogen ions in the solution can come only from the dissociation of the acid molecules. The dissociation equilibrium of the

<sup>24</sup> See Appendix.

acid is given by the equation  $\frac{[H^+][A^-]}{[HA]} = K_A$ , as described previously.

From this it follows that the hydrogen-ion concentration  $[H^+] = K_A \frac{[HA]}{[A^-]}$ .

For a weak acid, which is relatively little ionized, the difference between the concentration of undissociated acid molecules  $[HA]$  and the total acid concentration  $[Acid]$  is small. This difference becomes even less in the presence of a salt of the acid, since the salt ions  $A^-$ , by a mass action effect, repress still further the dissociation of acid molecules. Thus in a mixture of salt and acid we can substitute the total acid concentration  $[Acid]$  for the quantity  $[HA]$ , with very little error. Similarly the concentration of acid ions  $A^-$  derived from the dissociation of the acid molecules is very small compared to that furnished by the salt  $BA$  which is completely dissociated into  $B^+$  and  $A^-$  ions, so that we may consider the value of  $[A^-]$  to be determined primarily by the salt concentration. Although the salt is completely dissociated, because of the existence of interionic forces the effective concentration of salt ions,  $[A^-]$ , is somewhat less than the actual salt concentration. The ratio between these two quantities is, however, sensibly constant over the range of concentration that ordinarily comes into question, so that we may say  $[A^-]$  equals  $k[Salt]$ . Substituting  $k[Salt]$  for  $[A^-]$  in the above equation, and combining constants, we obtain the expression

$$[H^+] = K'_A \frac{[Acid]}{[Salt]}$$

This equation tells us that the hydrogen-ion concentration of a solution containing a weak acid and its salt is determined by the value of  $K'_A$  for the acid and by the ratio of acid concentration to salt concentration in the solution. While usable in the form given, it is more convenient to convert it into terms of pH rather than of  $[H^+]$ . If the logarithm of both sides of the equation is taken, and the signs reversed, we obtain:

$$-\log [H^+] = -\log K'_A - \log \frac{[Acid]}{[Salt]}$$

Now  $-\log [H^+]$  has already been defined as equal to pH. In an analogous way and for similar reasons we can define a term  $pK'_A$  as equal to  $-\log K'_A$ , and we can replace the negative expression  $-\log \frac{[Acid]}{[Salt]}$  by its equivalent, the positive expression  $\log \frac{[Salt]}{[Acid]}$ . Substituting these various terms in the above equation, we obtain:

$$pH = pK'_A + \log \frac{[Salt]}{[Acid]}$$

This is known as the Henderson-Hasselbalch equation, and is most generally useful. It tells us that the pH of a solution containing a weak acid and its salt is determined by a value  $pK'_A$ , which is constant for a

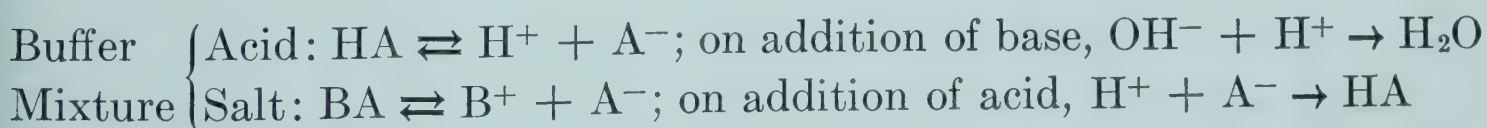

particular acid, and by the logarithm of the ratio of salt concentration to acid concentration in the solution. For example, the value of  $K'_A$  for acetic acid is approximately  $1.8 \times 10^{-5}$ , or  $10^{-4.7}$ . The  $pK'_A$  for acetic acid is therefore 4.7, and the pH of an acetic-acid-sodium-acetate buffer is given by the equation:

$$\text{pH} = 4.7 + \log \frac{[\text{Sodium acetate}]}{[\text{Acetic acid}]}$$

When  $[\text{Sodium acetate}] = [\text{Acetic acid}]$ , the pH is 4.7, since the ratio of salt to acid is 1, and  $\log 1 = 0$ . By varying the proportion of salt to acid in the mixture the pH will vary over a range of approximately 1.5 pH units below and above the  $pK'_A$  value—i.e., from pH 3.2 to pH 6.2. Outside of this range the equation is not applicable for this particular system. To cover other pH ranges, other weak acids with suitable  $pK'_A$  values are selected, so that by this means it is possible to prepare buffer solutions of almost any desired pH. This procedure is illustrated in the section on the preparation of pH standards which follows.

In addition to their value in the preparation of solutions of known pH, buffer solutions possess another property of fundamental importance in the living organism; namely, the ability to resist marked changes in pH on the addition of small amounts of strong acids or bases. It has been pointed out by Van Slyke that if a small amount of strong acid such as HCl is added to blood, which contains several buffers, the resulting change in pH in the direction of increased acidity may be only 1/1,000 of that which would have occurred if the blood were unbuffered. The action of a buffer solution in minimizing the effect on pH of added acid or base may be visualized as follows.

When base is added to the mixture the excess hydroxyl ions are removed by the hydrogen ions coming from the acid, which combine with them to form water. Upon the addition of acid the excess hydrogen ions from the added acid are removed by the salt ions, which combine with them to form more molecules of the relatively un-ionized weak acid. The reactions involved are as follows:

Thus the addition to a buffer solution of small amounts of base results merely in the production of more salt ions at the expense of an equivalent amount of the weak acid present; the addition of acid similarly results in the production of more weak acid at the expense of the salt. *The pH of the solution must inevitably change*, but this change in accordance with the demands of the Henderson-Hasselbalch equation is due to a change in the value of the logarithm of the ratio of salt concentration to acid concentration, which numerically is quite small in comparison to the concentration of  $\text{H}^+$  or  $\text{OH}^-$  ions added to the solution.

It is obvious from what has just been said that the more concentrated a buffer is, the smaller will be the change in pH on the addition of a given amount of strong acid or base—i.e., the greater will be the buffer power of the solution. Furthermore, if for example acid is added to a buffer solu-

FIG. 6. HYDROGEN-ION CONCENTRATION CHART.

This chart is, in slightly modified form, one prepared by Walpole from a large amount of data accumulated by Sørensen, Walpole himself, Michaelis, and a number of other authors. See Walpole: *Biochem. J.*, 8, 628 (1914). Indicators marked \* are used in titrations but not for pH determinations.

tion in an amount greater than that equivalent to the buffer salt present, the buffer capacity of the system will be exceeded and its ability to function as a buffer will disappear, since it will no longer consist of a mixture of buffer salt and acid. Another property of buffer solutions, which is also evident from inspection of the Henderson-Hasselbalch equation, is that they may be diluted considerably without appreciable change in pH, since the pH depends upon a concentration ratio rather than upon concentration itself.

The above discussion has been based entirely upon a consideration of buffers containing weak acids and their salts. An entirely analogous derivation can be made for solutions containing weak bases and their salts.

**Preparation of Standard Buffers of Known pH.** Fig. 6 indicates how standard solutions of definite hydrogen-ion concentration may be made up from a series of stock solutions, mixed in definite proportions. The stock solutions indicated on the chart were suggested by Sørensen and are as follows: 0.10 N HCl; 0.10 N NaOH; 7.505 g. glycine plus 5.85 g. NaCl per liter; 11.876 g.  $\text{Na}_2\text{HPO}_4 \cdot 2\text{H}_2\text{O}$  per liter;<sup>25</sup> 9.078 g.  $\text{KH}_2\text{PO}_4$  per liter; 21.008 g. citric acid in 1 liter of 0.20 N NaOH; 12.404 g. boric acid in 1 liter of 0.10 N NaOH. The other solutions are 0.20 N sodium acetate and 0.20 N acetic acid. Solutions of known hydrogen-ion concentration are prepared from these by mixing in the proportions indicated in Fig. 6, the abscissas representing parts of the relatively more alkaline constituent. Thus a mixture of seven volumes of the sodium acetate stock solution with three volumes of the stock acetic acid solution gives a mixture with a hydrogen-ion concentration of  $1 \times 10^{-5}$  (pH 5.0). The mixtures are most satisfactory through the ranges where the hydrogen-ion concentrations change most gradually—that is, through the flatter portions of the curves. The phosphate mixtures covering the range 5.3 to 8.0 are especially useful in biological work. The standard buffer solutions of Clark and Lubs, described below, are arranged to differ by even increments in pH instead of in component solutions, and are quite generally used.

**BUFFER SOLUTIONS OF CLARK AND LUBS:**<sup>26</sup> *Group 1.* To 50 ml. of

<sup>25</sup> This sodium phosphate may be obtained from laboratory supply houses or may be prepared by drying the powdered crystals containing 12 molecules of water by exposure to air at room temperature in shallow dishes for two weeks or more. To further insure dryness portions of the salt may then be placed in an incubator at 36° to 38° C. for one or two days.

The water used in preparing these solutions should be distilled water that has been boiled in a pyrex flask to eliminate  $\text{CO}_2$ . Stopper the flask while still hot with a rubber stopper carrying a soda-lime tube, and allow to cool. The sodium hydroxide must be carbonate-free (see Clark and Lubs' solutions). Protect the solutions from the  $\text{CO}_2$  of the air.

<sup>26</sup> The constituent solutions are prepared as follows:

0.2 M *potassium chloride*. Dissolve 14.912 g. in distilled water and make up to 1 liter. The salt should be recrystallized and dried at about 120° C. for two days.

0.2 M *acid potassium phthalate*. Dissolve 40.828 g. in distilled water and make up to 1 liter. The salt should be recrystallized from distilled water and dried at 110° to 115° C. for some hours.

0.2 M *acid potassium phosphate*. Dissolve 27.232 g. in distilled water and make up to 1 liter. The salt should be recrystallized from distilled water and dried at 110° to 115° C. for some hours.

0.2 M *boric acid in 0.2 M potassium chloride*. Dissolve 12.4048 g. of air-dried boric acid and 14.912 g. pure KCl in distilled water and make up to 1 liter.

0.2 N *sodium hydroxide*. Dissolve 100 g. of the best NaOH in 100 ml. of distilled water in an Erlenmeyer flask (pyrex). Cover the mouth of the flask with tinfoil, and allow the

0.2 M KCl add the indicated number of ml. of 0.2 N HCl and dilute to 200 ml. Indicator: thymol blue.

solution to stand overnight till the carbonate has settled. Cut a hardened filter paper to fit a Buchner funnel. Treat it with warm, strong (1:1) NaOH solution. Decant the soda and wash the paper first with absolute alcohol, then with dilute alcohol, and finally with large quantities of distilled water. Place the paper on the Buchner funnel and apply gentle suction until the greater part of the water has evaporated. Now pour the concentrated alkali upon the middle of the paper, spread it with a glass rod, and filter under suction. The clear solution is now diluted quickly with cold distilled water that has been boiled recently to remove CO<sub>2</sub>, to make approximately N NaOH (about 50 ml. per liter). Ten ml. of this are withdrawn and roughly standardized against N HCl. It is then diluted till it is approximately 0.2 N with CO<sub>2</sub>-free water and the solution poured into a paraffined bottle, to which a buret and soda-lime guard tubes have been attached. The solution is then accurately standardized against weighed amounts of the pure acid potassium phthalate. To do this, weigh accurately about 1.6 g. of the salt, dissolve in about 30 ml. of distilled water, add phenolphthalein, and titrate with the alkali till a faint but distinct and permanent pink is developed. A current of CO<sub>2</sub>-free air should be blown through the solution during the titration.

$$\frac{\text{g. of phthalate used} \times 1000}{204.14 \times \text{ml. NaOH required}} = \text{Normality of NaOH}$$

It is not necessary to make exactly 0.2 N, but the true strength must be considered in making standards.

0.2 N hydrochloric acid. Dilute concentrated HCl to 20 per cent. Distil, dilute the distillate, and standardize against the standard soda, using methyl red as the indicator. (Clark: *Determination of Hydrogen Ions*, 3d ed., Baltimore, Williams and Wilkins Co., 1928.)

**Theory of Indicators.** Indicators may usually be regarded as weak organic acids (or bases) whose un-ionized molecules exhibit one color whereas their anions (or cations) possess a different color. In the case of an indicator which behaves as a weak acid, for example, we have the following equilibrium reaction:

Applying the law of mass action to this ionization of the indicator acid, we get

$$\frac{[\text{H}^+][\text{Indicator}^-]}{[\text{H Indicator}]} = K', \text{ or } \frac{[\text{H}^+]}{K'} = \frac{[\text{H Indicator}]}{[\text{Indicator}^-]}$$

where  $K'$  is called the apparent dissociation constant of the indicator. The color imparted to a solution by the indicator depends upon the relative proportions of the two forms of the indicator present in the solution, and this, in turn, depends upon the ratio  $[\text{H}^+]/K'$ . Since  $K'$  is a fixed number, specific for each indicator, the color formed will depend upon the hydrogen-ion concentration of the solution. In the case of brom cresol green, for example,  $K' = 10^{-4.7}$ ; the undissociated molecules are yellow while the anions are blue. For this indicator, therefore, the above equation may be written

$$\frac{[\text{H}^+]}{10^{-4.7}} = \frac{[\text{Yellow molecules}]}{[\text{Blue ions}]}$$

If brom cresol green is added to a buffer solution whose hydrogen-ion concentration is  $10^{-4.7}$  (i.e., is numerically equal to the value of  $K'$  for the indicator), then according to the above equation the concentrations of yellow molecules and blue ions in the solution must be equal. In this case therefore the solution will assume the green color which results when equal numbers of these yellow and blue particles are mixed together. If, on the other hand, the indicator is added to a series of solutions whose

hydrogen-ion concentrations are progressively greater than  $10^{-4.7}$ , then, as the hydrogen-ion concentrations increase, the proportion of yellow molecules to blue ions in these mixtures will also increase. Finally, at a hydrogen-ion concentration of about  $10^{-3.8}$  ( $\text{pH} = 3.8$ ), the eye can no longer detect the presence of blue ions in the mixture. At this pH the solution exhibits the yellow color of the undissociated indicator molecules, and further increases in hydrogen-ion concentration will not produce any perceptible changes in color. Similarly in solutions whose hydrogen-ion concentrations are less than  $10^{-4.7}$  the blue anions predominate, and as the hydrogen-ion concentration decreases a point is reached where it is the yellow molecules which no longer can be detected in the mixture. At this pH (approximately 5.4), the solution exhibits the blue color of the indicator ions, and further reduction in hydrogen-ion concentration produces no perceptible change in the color. Thus in solutions having a pH between 3.8 and 5.4 the indicator exists as a mixture of yellow molecules and blue ions and the relative amounts of each of these substances in the mixture, and the colors formed, vary with the hydrogen-ion concentrations of the solutions. In this range therefore brom cresol green can be used to determine the pH of an unknown solution by comparing the color formed with the colors produced when the indicator is added to a series of standard buffer solutions of known pH. In solutions whose pH is less than 3.8 or more than 5.4, however, the eye can detect the presence of only one form of the indicator and variations in pH are no longer accompanied by visible changes in color. The pH of such solutions, therefore, cannot be determined by means of this particular indicator. Since each indicator has its own value for  $K'$  it follows that for each indicator there is a definite range of hydrogen-ion concentration in which the indicator exists as a mixture of the ionized and un-ionized forms, and in which variations in hydrogen-ion concentration will be accompanied by visible changes in color. The problem of determining the pH of an unknown solution by means of indicators depends, therefore, upon the selection of an indicator whose effective range includes the pH of that particular solution.

**Uses of Indicators.** Both the concentration of free hydrogen ions in a solution and its titratable acidity (or alkalinity)—i.e., the total amount of hydrogen (or hydroxyl) ions which the solution is capable of yielding on complete dissociation—may be determined by the use of proper indicators. For the latter determination the solution is titrated with standard alkali or acid in the presence of an indicator which serves as an index of the end point of the reaction. The indicator used for this purpose should be one which gives a sharp color change when an equivalent amount of the standard acid or alkali has been added. If at this point the reaction of the solution is practically neutral ( $\text{pH} 7$ ), an indicator changing color at about this reaction (litmus or rosolic acid) would be suitable. On the other hand if we add 20 ml. of 0.1 N NaOH to 20 ml. of 0.1 N acetic acid the resulting solution will be not neutral, but rather slightly alkaline due to hydrolysis. The sodium acetate formed will react with the water to produce some NaOH and an equivalent amount of acetic acid. Acetic acid is a weak acid and will dissociate few hydrogen ions, but NaOH is a

strong base and dissociates completely, liberating OH ions which, being in excess, cause the solution to be alkaline. In titrating weak acids such as acetic and most other organic acids it is therefore necessary to use an indicator which changes color in a slightly alkaline medium. Phenolphthalein has been found to be suitable. For similar reasons the titration of weak bases such as ammonia necessitates the use of an indicator which changes color in an acid medium. Methyl red and alizarin red are often used in such cases. If a strong base such as NaOH is titrated with a strong acid such as HCl, almost any common indicator may be used, because one drop of 0.1 N solutions of these will throw the hydrogen-ion concentration so far beyond that of neutrality as to pass the turning point of any of these indicators. (For further discussion see electrometric titration method, p. 50, and titration curves, Fig. 11, p. 50.)

In making use of indicators for determination of hydrogen-ion concentration, the first problem is to choose an indicator whose effective range includes the pH of the unknown solution. That is, the indicator used must be one which, when added to the unknown solution, will exist as a mixture of both the ionized and un-ionized forms, so that the color will be characteristic of the pH. After selection of the proper indicator the unknown is treated with a measured volume of this indicator and the color obtained is compared with those produced when the same amount of indicator is added to a series of buffer solutions of known hydrogen-ion concentration. The pH of the unknown is considered to be the same as that of the buffer solution which yields exactly the same shade of color. For use in the determination of the hydrogen-ion concentration of a solution an indicator is selected which shows a satisfactory gradation in color through the range in question, which is not readily affected by the presence of neutral salts or other substances likely to be present, and the color of which does not fade too rapidly. The ranges through which a number of indicators may be used with satisfactory results for the determination of hydrogen-ion concentrations are indicated in Fig. 6. The sulfonphthalein series of Clark and Lubs is especially brilliant and reliable.

## EXPERIMENTS ON DETERMINATION OF HYDROGEN-ION CONCENTRATION

**1. Colorimetric Determination of Hydrogen-ion Concentration.** The first step in this procedure is to determine the approximate pH of the unknown solution so that a suitable indicator may be selected. Treat a small (about a 1-ml.) portion of the unknown solution with 1 drop of an indicator<sup>27</sup> solution,

<sup>27</sup> Indicators may be obtained in powder form or in prepared solutions from LaMotte Chemical Products Co., W. A. Taylor and Co., or Hynson, Westcott, and Dunning, all of Baltimore, Md. 0.04 per cent solutions of all of the Clark-Lubs series of indicators are used. For many purposes 0.04 per cent solutions of the indicators in 95 per cent alcohol may be used. Clark and Lubs prefer to use aqueous solutions of the alkali salts. To prepare these stock solutions rub 0.1-g. portions of dry powder in an agate mortar with the following quantities of 0.05 N NaOH: phenol red 5.7 ml., brom phenol blue 3.0 ml., cresol red or meta cresol purple 5.3 ml., thymol blue 4.3 ml., brom thymol blue 3.2 ml., brom cresol green 2.9 ml., chlor phenol red 4.7 ml. If exact equivalents are not desired, solution is more readily obtained by using 1.1 equivalents of NaOH. When solution is complete, dilute to 25 ml. with water. Dilute portions of these stock solutions ten times to get 0.04 per cent solutions. Other indicator solutions may be made up as follows: Alizarin yellow R (*p*-nitrobenzene-azo-salicylic acid), methyl orange, tropaeolin O, tropaeolin OO, and tropaeolin OOO in 0.01 per

and compare the color obtained with those resulting when 1 drop of the indicator is added to the same volume of 0.1 N HCl (acid color) and 0.1 N NaOH (alkaline color). If the color obtained with the unknown is intermediate between the acid and alkaline colors of the indicator, the pH of the unknown lies within the effective range of this indicator and it may be used for the colorimetric determination of pH as described below. If on the other hand the unknown shows either the full acid or full alkaline color with the indicator selected, it is unsuitable and another indicator must be tried in a similar manner, until an indicator has been found whose effective range includes the pH of the unknown solution.

When the proper indicator has been selected, look up the effective pH range of this indicator (see chart, p. 34, or table, p. 381). Into a series of clean test tubes of clear (preferably pyrex) glass of uniform internal diameter (about 15 mm.), measure 10-ml. portions of standard buffer solutions covering this range, preferably in steps of 0.2 pH unit. Add 10 drops (0.5 ml.) of indicator solution to each tube and mix. Prepare a 10-ml. portion of the unknown solution in a test tube similar to that containing the standards and with the same amount of added indicator. Compare the unknown against the standards, using a comparator block (Fig. 7). The pH of the standard most closely matching the unknown is the pH of the unknown. It should be possible to interpolate between standards, thus attaining a precision of 0.1 pH unit, if the standards differ by 0.2 pH.

For approximate orientation in the preliminary trials, suitable use may be made of the ordinary laboratory indicators (litmus, phenolphthalein, methyl orange—see Fig. 6), but the final choice of indicator should be based upon trial with those indicators which have been specially selected for use in the colorimetric determination of hydrogen-ion concentration. In this connection it is well to remember that thymol blue has two effective pH ranges (1.2 to 2.8, and 8.2 to 9.8), the alkaline color for the first range as well as the acid color for the second range being obtained with some solution having a pH between 3 and 8, such as dilute acid potassium phosphate solution. In measuring out the indicators the dropping pipet should be held perpendicularly so that drops of constant size are obtained. In measuring out buffer solutions with a pipet the latter should not be blown out and if used for another solution must first be rinsed very thoroughly with distilled water from a flask which has not been blown through (because of the  $\text{CO}_2$  in expired air).<sup>28</sup> Color comparisons should be made in a good light using a sheet of white paper as a background.

If the stock solutions of Sørensen are used, 10-ml. portions of standard solutions may be made up from these as required. The stock solutions are measured from burets and the proportions required for a certain pH may be found in Fig. 6. Let us suppose that the unknown solution has been found to have a pH within the range of phenol red (6.6 to 8.2). This range is covered by the phosphate buffer mixtures. Measure out 5 ml. of the acid phosphate and 5 ml. of the alkaline phosphate, mix, and add 10 drops of indicator. If the same tint is obtained as with the unknown, consult the chart. It will be found that this phosphate mixture has a pH of 6.8 and the pH of the unknown must also be 6.8. If the same tint is not obtained on the first attempt make other trials

---

cent aqueous solutions. Methyl red, saturated solution in 50 per cent alcohol. Neutral red, 0.01 per cent in 50 per cent alcohol. *p*-Nitrophenol, 0.04 per cent in 6 per cent alcohol. Phenolphthalein, 0.5 per cent in 50 per cent alcohol. Azolitmin in aqueous solution.

<sup>28</sup> For the standards it is best to use bottles whose stoppers carry 10-ml. pipets. Where used by more than one person, bulbs may be used to fill the pipets.

using proportions of 4:6, 3:7, etc. For other ranges of pH use other indicators and other buffer solutions in the same manner.

If the unknown solution possesses a color of its own either of two procedures may be resorted to. The first method is to add to the standard, before any indicator is added, enough inert coloring matter to match that in the unknown and then add indicator to both.<sup>29</sup> A better method which may also be applied to moderately turbid solutions was suggested by Walpole. The comparator shown in Fig. 7 is used.<sup>30</sup> The colored fluid plus indicator is placed in a test tube in hole 3 and the standard solutions for comparison on each side in holes 1 and 5. Then opposite the standards in holes 2 and 6 are placed tubes containing the colored unknown solution without added indicator and in hole 4 a tube containing water only. Comparison is made through the apertures A, B, and C.

## 2. Colorimetric Determination of Hydrogen-ion Concentration Without Use of Buffer Solutions.<sup>31</sup>

This procedure is most simply carried out using indicators changing from colorless to a single colored form such as phenolphthalein or the nitrophenols. Within the effective range of the indicator, the depth of color varies with the pH and depends upon the amount of dissociated indicator present. The amount of completely dissociated indicator required to give the same tint as the unknown is a measure of the pH of the latter. The standards are made up by adding measured amounts of indicator solution to portions of solution in which the indicator gives its maximum color (complete dissociation).

To 10 ml. of unknown solution in a test tube add 1 ml. of indicator solution.<sup>32</sup> To another tube (the standard) add 9 ml. of a solution giving the

FIG. 7. COMPARATOR BLOCK.

<sup>29</sup> Solutions suitable for this purpose include Bismarck brown, tropaeolin O and tropaeolin OO in 0.02 per cent aqueous solutions, cotton blue 0.01 per cent, methyl violet 0.002 per cent, methyl orange 0.01 per cent, all in water; curcumine 0.02 per cent in 60 per cent alcohol, and helianthin II 0.01 per cent in 80 per cent alcohol.

<sup>30</sup> A comparator may be made by boring 6 holes in pairs in a block of soft wood, the paired holes being as close together as possible and just large enough to hold ordinary test tubes. Smaller holes are then bored perpendicular to these. Stain black with an alcohol wood stain. A sheet of ground glass placed between the light source and the tubes is helpful.

<sup>31</sup> Michaelis and Gyemant: *Biochem. Z.*, **109**, 165 (1920).

<sup>32</sup> Michaelis suggests the following indicators:

| Name                             | Composition              | $pK'$<br>18° C. | Range<br>of pH | Stock Solution of<br>Indicator                    |
|----------------------------------|--------------------------|-----------------|----------------|---------------------------------------------------|
| $\beta$ -Dinitrophenol. . . . .  | 1-oxy-2, 6-dinitrobenzol | 3.69            | 2.2-4.0        | 0.1 g.: 300 ml. H <sub>2</sub> O                  |
| $\alpha$ -Dinitrophenol. . . . . | 1-oxy-2, 4-dinitrobenzol | 4.06            | 2.8-4.5        | 0.1 g.: 200 ml. H <sub>2</sub> O                  |
| $\gamma$ -Dinitrophenol. . . . . | 1-oxy-2, 5-dinitrobenzol | 5.15            | 4.0-5.5        | 0.1 g.: 200 ml. H <sub>2</sub> O                  |
| <i>p</i> -Nitrophenol. . . . .   | ..                       | 7.18            | 5.2-7.0        | 0.1 g.: 100 ml. H <sub>2</sub> O                  |
| <i>m</i> -Nitrophenol. . . . .   | ..                       | 8.33            | 6.7-8.4        | 0.3 g.: 100 ml. H <sub>2</sub> O                  |
| Phenolphthalein. . . . .         | ..                       | 9.73            | 8.5-10.5       | 0.04 g.: 30 ml. alcohol + 70 ml. H <sub>2</sub> O |

maximum color with the indicator (e.g., 0.02 N NaOH) and then add indicator solution diluted ten times from a microburet or Mohr pipet until a color is obtained which on diluting the standard to the same volume as the unknown (11.0 ml.) matches that of the unknown. If the first standard does not exactly match, make a second one; if more than 2 ml. of diluted indicator are needed, repeat, using undiluted indicator.

CALCULATION.

$$\text{pH} = \text{p}K' + \log \frac{C}{1 - C}$$

where  $\text{p}K'$  is a constant for the indicator (consult table) and  $C$  is the volume in ml. of indicator added to the standard, expressed on an undiluted basis. If 1 ml. of diluted indicator were used (0.1 ml. of undiluted) and the indicator is *p*-nitrophenol ( $\text{p}K'$  7.18) we have  $\text{pH} = 7.18 + \log \frac{0.1}{0.9} = 7.18 + (\log 0.1 - \log 0.9) = 7.18 + (-1 - (9.95 - 10)) = 7.18 - 0.95 = 6.23$ . A chart giving values of  $\log \frac{C}{1 - C}$  is convenient in making calculations.<sup>33</sup>

**Other Colorimetric Methods for Determining Hydrogen-ion Concentration.** The method without buffers may also be applied to two-color indicators (Gillespie). In this case each standard consists of two tubes set one behind the other in the Walpole comparator. One tube contains for example a known amount of phenol red in alkaline solution (red) and the other in acid solution (yellow). By varying the proportions any shade of this indicator may be obtained. For further details, see Clark.

Indicator paper ("Hydrion," "Accutint," etc.) may also be used for the determination of pH. Such paper is convenient and sufficiently accurate for many purposes.

**3. Comparison of Hydrogen-ion Concentration and Titratable Acidity.** (A) Determine colorimetrically the hydrogen-ion concentration of a 0.01 N solution of hydrochloric acid using thymol blue as an indicator and of a 0.01 N acetic acid solution using brom cresol green as an indicator. Note the great difference between the true acidities of the two solutions.

Titrate 10-ml. portions of 0.01 N hydrochloric acid and of 0.01 N acetic acid with 0.01 N NaOH, using phenolphthalein as an indicator. Note that identical results are obtained for the titratable acidities of the two.

(B) Mix equal portions of M/15 potassium dihydrogen phosphate and M/15 disodium phosphate (see chart). Note that the mixture is practically neutral to litmus. Titrate one 10-ml. portion of this mixture with 0.1 N NaOH, using phenolphthalein as an indicator. Titrate another portion with 0.1 N HCl solution, using methyl orange. Explain results.

**4. Differential Titration of Strong and Weak Acids.** Mix 5.0 ml. of 0.1 N HCl with 5.0 ml. of 0.1 N acetic acid. Add thymol blue, and titrate with 0.1 N NaOH to pH 2.8 to 3.0 (use a pH standard as a control). Read the buret, then continue titrating until the indicator changes to blue (pH 8.5). Again read the buret. Compare the buret readings with those expected if (a) only the strong acid were titrated and (b) both acids were completely titrated. Explain. This principle finds clinical application in the titration of gastric juice.

<sup>33</sup> For chart, see Michaelis: *Practical Physical and Colloid Chemistry*, translated by Parsons, Cambridge, W. Heffer and Sons, 1925; and Clark: *Determination of Hydrogen Ions*, 3d ed., Baltimore, Williams and Wilkins Co., 1928.

## ELECTROMETRIC DETERMINATION OF HYDROGEN-ION CONCENTRATION

**Electrode Potentials.** If an excess of solid glucose is placed in water, some of the molecules of the solid, being in a continual state of vibration, escape into the liquid. As the molecules of glucose in solution accumulate, some of them collide with the particles of solid and are retained. An equilibrium is finally established in which there is a balanced exchange of molecules between the solid and the solution. At this stage the solution is saturated with glucose and the solution pressure of the solid is said to be equal to the osmotic pressure of the dissolved substance.

FIG. 8. DIAGRAM OF RELATIONS AT SURFACE OF A METAL DIPPING INTO SOLUTIONS CONTAINING ITS IONS IN DIFFERENT CONCENTRATIONS.

( $P$  = solution pressure of the metal;  $p$  = osmotic pressure of metallic ions.)

If a strip of metal (electrode) is dipped into water, it also tends to dissolve owing to its solution pressure,  $P$ . The metal goes into solution as positive ions leaving its electrons (presumably less firmly bound valence electrons) behind as a negative charge on the electrode. This charge, by attracting the positive ions of metal already in solution, builds up an electrical double layer at the interface between electrode and solution which opposes the entrance of any more positive ions into the solution, and the process of solution ceases therefore when this charge becomes large enough to prevent the further separation of positive ions from the metal. Although equilibrium is established before a measurable quantity of the metal dissolves, since the charge on each ion is comparatively large, a measurable potential difference is developed between the electrode and the solution.

When a metal is dipped into a solution of one of its salts the conditions are somewhat altered because the positive ions of the metal already in solution oppose the separation of more ions from the metal. The point of equilibrium therefore will depend upon the relative values of the two opposing forces: the solution pressure ( $P$ ) of the metal and the osmotic pressure ( $p$ ) of its ions in solution. We may therefore distinguish three possibilities (see Fig. 8):

1.  $P > p$ . In this case the metal continues to send positive ions into the solution until the accumulated charges oppose further action. The metal thus acquires a negative charge relative to the solution.

2.  $P < p$ . In this case the positive ions in solution deposit on the metal, yielding to it their positive charges, until the accumulated charges oppose further deposition. The metal thus acquires a positive charge relative to the solution.

3.  $P = p$ . In this case there is neither solution nor deposition and no potential difference develops between the metal and the solution.

Nernst has shown by thermodynamic reasoning that the potential difference between a metal and a solution of one of its salts is given by

$$E = \frac{RT}{nF} \ln \frac{P}{p}$$

where  $E$  = electrode potential,  $R$  = gas constant = 8.316 joules per degree,  $T$  = absolute temperature,  $n$  = valency of metal ion,  $F$  = faraday = 96,500 coulombs,  $P$  = solution pressure, and  $p$  = osmotic pressure of metal ions in solution. (The symbol "ln" stands for the natural logarithm.)

From this equation it becomes evident that, since  $RT/F$  is a constant for any given temperature, the magnitude and sign of the electrode potential,  $E$ , is determined by  $n$  and  $P$ , which depend solely upon the nature of the metal used, and  $p$ , which is a function of the concentration of metal ions in solution. If therefore we have two electrodes of the same metal dipping into solutions of different concentrations, the two electrode potentials will be different. And if we make suitable connections<sup>34</sup> between the two electrodes and the two solutions an electrical current will pass from one electrode to the other, the electromotive force of which will be equal to the difference between the two electrode potentials—i.e.

$$\begin{aligned} E &= E_1 - E_2 \\ &= \frac{RT}{nF} \ln \frac{P_1}{p_1} - \frac{RT}{nF} \ln \frac{P_2}{p_2} \\ &= \frac{RT}{nF} (\ln P_1 - \ln p_1 - \ln P_2 + \ln p_2) \\ &= \frac{RT}{nF} \ln \frac{p_2}{p_1} \text{ (since } P_1 = P_2 \text{ for the same metal)} \end{aligned}$$

If osmotic pressure is regarded as proportional to concentration, we may replace  $p_1$  and  $p_2$  by  $c_1$  and  $c_2$ , and get

$$E = \frac{RT}{nF} \ln \frac{c_2}{c_1}$$

<sup>34</sup> The two solutions are usually connected by a salt bridge consisting of an inverted U-tube filled with saturated KCl solution. This tends to eliminate any differences of potential which may be built up at the junction of the two solutions by the unequal diffusion of the ions. The electrodes are connected by wire in the ordinary manner.

An arrangement such as here described is known as a concentration cell, and the above equation permits us to calculate the concentration of metal ions in an unknown solution from the electromotive force developed when that solution is combined in a cell with a similar solution of known ionic concentration. It should be noted that the concentration calculated by the use of the above equation will be that of electromotively active ions, which is not necessarily the same as that obtained by ion conductivity or other means. For a further discussion of this point, the reader is referred to Clark.

**The Hydrogen Electrode.** A strip of platinum, coated with platinum black and saturated with hydrogen gas, acts exactly as the metal electrodes described above when dipped into a solution containing hydrogen ions. We can therefore construct a concentration cell by dipping two such electrodes into two solutions of different hydrogen-ion concentrations, and, if the concentration of hydrogen ions in one solution is kept at a known constant value, we can use the electromotive force developed by such a cell to calculate the hydrogen-ion concentration in the second unknown solution. If the concentration of hydrogen ions in the known solution is normal, the equation for the electromotive force becomes

$E = \frac{RT}{nF} \ln \frac{1}{[H^+]}$ . By substituting the values for  $R$ ,  $T$ ,  $n$ , and  $F$  at  $25^\circ \text{C}$ .

and multiplying by 2.303 to change from the natural to the common system of logarithms, we get  $E = 0.059 \log \frac{1}{[H^+]}$  or  $E = 0.059 (-\log$

$[H^+])$ . Hydrogen-ion concentrations, following the convention introduced by Sørensen, are usually expressed in terms of pH; by definition,

$\text{pH} = -\log [H^+]$ . Therefore,  $E = 0.059 \text{ pH}$  or  $\text{pH} = \frac{E}{0.059}$ .

In practice it is convenient to use, instead of a hydrogen electrode in a normal solution of hydrogen ions, a calomel electrode which has been standardized against such a solution. A calomel electrode is made up of mercury in contact with calomel in a solution of potassium chloride, the latter being either normal, tenth-normal, or, more often, saturated. The normal hydrogen electrode is approximately 0.25 volt more positive than the saturated calomel electrode<sup>35</sup> so that the difference of potential between the calomel electrode and the unknown will be 0.25 volt greater than that between the latter and the normal hydrogen electrode. Therefore, using the saturated calomel electrode at a temperature of  $25^\circ \text{C}$ .,

$\text{pH} = \frac{E - 0.246}{0.059}$ . We may read  $E$  directly in volts on a voltmeter, or by

means of a potentiometer, so that the calculation becomes very simple. Variations of pH with  $E$  may be plotted in the form of a curve. In some instruments the voltmeter is graduated to read pH directly.

Regardless of the types of electrodes used in the chain, the measurement of  $E$  must be conducted by means which do not entail an appreciable flow of current from the system, because such a flow introduces polarization

<sup>35</sup> This figure varies with the temperature and with the concentration of KCl solution in the calomel electrode (see values for  $E_0$  in the table on p. 48).

effects at the electrodes. The potentiometric method is ideally adapted for this purpose. The principles involved in this method are described in detail in Clark's book, and also in the descriptive literature which accompanies the special apparatus required.<sup>36</sup>

Hildebrand's method, described below, requires only such electric apparatus as is usually found in any laboratory, and serves to illustrate

FIG. 9. ARRANGEMENT OF APPARATUS FOR ELECTROMETRIC DETERMINATION OF HYDROGEN-ION CONCENTRATION. (METHOD OF HILDEBRAND.)

*H* is the hydrogen electrode, *C* the calomel electrode, *V* a voltmeter, *G* a galvanometer, *R* a rheostat, *A* the beaker containing the unknown solution, and *B* a connecting vessel.

the principles of the electrometric method. The use of a potentiometer instead of the voltmeter indicated increases the accuracy of the determination and is to be preferred.

**Determination of Hydrogen-ion Concentration by Hildebrand's Method.**<sup>37</sup> Set up the apparatus as indicated in Fig. 9. The battery may be an ordinary dry cell. The voltmeter *V* should have a range of 1.2 volts and scale divisions to 0.01 volt. The portable galvanometer *G* should have a sensitivity of at least one megohm. A capillary electrometer may be used in place of the galvanometer. The rheostat *R* may be a tubular wire rheostat having at least 150 turns of wire. *K* is a contact key for opening and closing the circuit. *C* is

<sup>36</sup> Assemblies suitable for various purposes may be obtained from manufacturers and dealers. The equipment manufactured by Leeds and Northrup Co., Philadelphia, has been widely used.

<sup>37</sup> Hildebrand: *J. Am. Chem. Soc.*, 35, 847 (1913).

the calomel electrode.<sup>38</sup> *H* is a hydrogen electrode of the Hildebrand type especially suitable for solutions not containing protein. The Clark electrode is a type frequently employed in biochemical work and may be used with a shaking device to assist in obtaining equilibrium rapidly.

The essential part of the hydrogen electrode is the piece of platinum foil which is to dip into the unknown solution. This must be given a spongy coat of platinum black so that it will retain as much hydrogen as possible and must be saturated with hydrogen just before use.<sup>39</sup>

The unknown solution is placed in beaker *A*. The calomel electrode is clamped in place, as also is the prepared hydrogen electrode. A stream of hydrogen<sup>40</sup> is passed through the side arm of the hydrogen electrode so that it bubbles up through the solution at the rate of about two bubbles per second. Beaker *B* contains saturated KCl solution. The connecting tube contains saturated KCl made up in warm 3 per cent agar and allowed to solidify in the tube. This prevents syphoning between *B* and *A*.

Stir the solution well: an automatic stirring device is best for this purpose. Move the sliding contact on the rheostat until the voltage drawn from the dry cell is equal to that produced in unknown solution. This is indicated by the fact that no current passes through the galvanometer when the contact key *K* is pressed down, and there is therefore no deflection of the needle. Until a balance is reached the spring contact key should be closed only momentarily by a slight tap. At the balance point read the voltmeter.

CALCULATION OF pH. See the discussion preceding *Determination*. At 25° using saturated calomel electrode  $\text{pH} = (E - 0.246)/0.059$ . If for example the voltmeter reads 0.652 then  $\text{pH} = (0.652 - 0.246)/0.059 = 7.0$  and the solution possesses a neutral reaction. Corrections for different electrodes and temperatures are given in the following table. This apparatus should have an accuracy of about 0.1 pH. Test the apparatus first, using buffer solutions of known pH.<sup>41</sup>

---

<sup>38</sup> Calomel Electrode: Place about 3 ml. of carefully purified mercury in the bottom of the electrode vessel. Rub together mercury and mercurous chloride (calomel) with a little saturated KCl solution to form a paste. Place a layer of this paste about a half inch thick over the mercury and fill the vessel to the end of the side tube with saturated KCl solution. If it is desired to make a normal or tenth-normal calomel electrode corresponding solutions of KCl should be used instead of the saturated solution. It is convenient to make a permanent connection between the upper side arm and a reservoir bottle containing KCl solution. By running a little of the solution through the calomel cell before each series of determinations the side arm may be washed free from materials that may have diffused up into it. The stop-cock of this electrode should be tight but should not be greased. A typical calomel electrode is shown in *C*, Fig. 9.

<sup>39</sup> Clean the platinum electrode thoroughly with chromic acid. Connect with the negative pole of a dry cell and connect another strip of platinum with the positive pole. Dip both in a dilute (2 per cent) solution of platinic chloride. Electrolyze for 10 to 15 minutes, frequently reversing the current. Dip into 10 per cent sulfuric acid, with the electrode as the cathode, and let the current run for a few minutes. The platinum is saturated with hydrogen. Wash with distilled water. Keep under distilled water when not in use. The platinum coat should last for several weeks but must be saturated with hydrogen just before use. Instead of a strip of platinum a wire about 1 mm. in diameter slightly flattened at the end may be used. Equilibrium with such an electrode may be brought about more rapidly. Shorter periods of electrodeposition produce electrodes which come to equilibrium more rapidly but which are not so permanent.

<sup>40</sup> Hydrogen may be purchased in cylinders, or may be prepared by electrolysis of an NaOH solution or from pure zinc. To purify pass through a wash bottle containing alkaline pyrogallol solution and two bottles containing water. Connect one of these bottles with a third tube dipping below the surface of mercury in another vessel. This acts as a safety. With gas tanks a gas regulator for adjusting flow is desirable.

<sup>41</sup> A suitable solution tenth-normal with respect to both acetic acid and sodium acetate may be used. At 25° with the saturated calomel electrode this gives 0.519 volt and with the 0.1 N electrode 0.6108 volt. Mix 50 ml. N NaOH and 100 ml. N acetic acid with water to make 500 ml.

The hydrogen electrode under carefully defined conditions is the ultimate standard of reference for the determination of hydrogen-ion concentration in aqueous solution. The technical difficulties associated with its routine use, as well as its limitations under certain conditions, have led to a search for other electrodes suitable for the electrometric determination of pH. Among those which have found use may be mentioned the antimony electrode<sup>42</sup> the quinhydrone electrode, and the glass electrode. The glass electrode has superseded all others for most purposes.

**The Glass Electrode.** One type of glass electrode in common use consists of a bulb of special glass which is filled with some standard electrolyte, such as 0.1 N HCl, in contact with a suitable metallic electrode. When this bulb is immersed in an unknown solution a potential difference develops between the two solutions, the magnitude of which depends upon the hydrogen-ion concentration of the solution. This potential difference is measured as with the hydrogen electrode by combining the glass electrode with some standard half cell, such as the saturated calomel electrode, and measuring the voltage of the system. Because of the high resistance of the glass, however, the usual methods of determining the voltage, such as those used with the hydrogen electrode, cannot be used. Instead, a vacuum-tube amplifier is inserted in the potentiometer circuit. Various types of apparatus (*pH meters*) using this type of amplification and calibrated to read directly in pH units are available. Since they make use of various types of electrodes, amplification circuits, etc., the literature supplied with each instrument should be consulted for further details concerning the construction and operation of that instrument.

In general the determination of pH with a pH meter is quite simple. The solution is placed in a small container and the glass electrode and calomel electrode immersed in the solution. The potentiometer circuit is closed and adjusted until the null point is reached. The pH may then be read directly. Two general precautions are ordinarily necessary. The pH meter must be calibrated frequently by checking against a standard buffer of known pH, readjusting the scale setting if necessary. Failure to

<sup>42</sup> For review, see Perley: *Ind. Eng. Chem., Anal. Ed.*, **11**, 316 (1939).

do this is the most frequent cause of error with a pH meter, since the calibration may change significantly from time to time, particularly if the glass electrode is new or has been allowed to become dry. It is best to keep both glass and calomel electrodes immersed in water when not in use. The temperature of the solution will also influence the determination of pH. In the Beckman pH meter illustrated (Fig. 10), for example, the temperature control must be set at the temperature of the unknown solution before the reading is made.

The glass electrode is used for determinations of pH in all types of biological systems. Since (unlike the hydrogen electrode) it does not cause

FIG. 10. GLASS-ELECTRODE APPARATUS (BECKMAN).

Glass electrode shown at right (*above*) and calomel electrode (*below*).

gas to bubble through the solution, it may be used on systems like blood which contain dissolved  $\text{CO}_2$ . The sample is not contaminated, so that the method is especially applicable where the amount of material is limited. Electrodes are available which require only a few tenths, or even hundredths, of a milliliter of solution for each determination. Determinations with the glass electrode are rapid, and with most instruments the accuracy is within 0.05 pH. It may be used on unbuffered, colored, or turbid solutions and solutions containing sediments. With the ordinary glass electrode, determinations are accurate up to a pH of 10 or even higher, provided the solutions do not contain appreciable quantities of sodium, lithium, or potassium ions. Sodium ions, especially, exert a considerable effect on determinations in solutions with a pH of 9 or above, when they are present in a concentration of normal or greater. Corrections may be applied in such cases (Dole). Special electrodes have been

developed for use in strongly alkaline solutions, for solids such as cheese, and for many other purposes.

**Electrometric Titration of Acids and Bases.** In many cases the use of indicators in titration is unsatisfactory because of color or turbidity of solutions to be examined or the presence of buffer substances which make the end point uncertain. The hydrogen or glass electrodes may be used in such cases in titrating solutions to a definite acidity or alkalinity. This method also makes it possible to follow the changes in acidity during the course of a titration and gives information as to the character of the

FIG. 11. TITRATION CURVES OF VARIOUS ACIDS, OBTAINED BY ELECTROMETRIC MEASUREMENT.

Twenty ml. of 0.1 N hydrochloric and acetic acids used. *Phosphoric acid* about  $\frac{2}{3}$  molar. *Boric acid*, saturated solution.

acids or bases in solution. Some applications of this method are illustrated in Fig. 11.

**Procedure.** The apparatus already described and illustrated in Fig. 9 may be used. The unknown solution is placed in beaker A, into which are introduced both the hydrogen and calomel electrodes. Beaker B and the connecting tube are omitted. Hydrogen is bubbled through the solution and acid or alkali added from a buret with stirring. At intervals read the voltmeter. Plot a curve of voltage or pH against milliliters of acid or alkali added. Neutralization is indicated by a rapid change of voltage or pH. Di- or tribasic acids or bases may show two or more such changes. See the curve for titration of phosphoric acid (Fig. 11).

The glass-electrode pH meter is particularly suitable for this purpose. Special electrodes with long leads are available, for direct titration in an ordinary beaker.

As will be seen from Fig. 11, in the titration of a strong acid such as hydrochloric acid with a strong base such as sodium hydroxide, the change

in  $[H^+]$  at the end point is very sharp because, as long as even 0.1 ml. of the acid remains unneutralized, the pH is still quite low and 0.1 ml. of 0.1 N NaOH in excess gives a very large increase of pH. Evidently either methyl orange, litmus, or phenolphthalein may be used in the titration. With acetic acid however the beginning  $[H^+]$  is lower because this acid is weakly dissociated. The change in pH is at first fairly rapid because the sodium acetate formed yields acetate ions which repress the ionization of the acid. As the titration is continued the ionization of the acid is almost completely repressed by the larger amounts of acetate formed. When an equivalent amount of alkali has been added, the reaction is alkaline owing to slight hydrolysis of the sodium acetate to form acetic acid (nearly all undissociated) and highly dissociated NaOH. The actual end point of the titration is therefore on the alkaline side and phenolphthalein is the proper indicator.

Fig. 11 shows also how it is possible to titrate the first hydrogen of phosphoric acid using methyl orange as an indicator and the second using phenolphthalein; the third cannot be titrated because the change is too gradual. Note also that boric acid cannot be titrated with phenolphthalein as an indicator.

**Electrometric Oxidation and Reduction Titrations.** When an ion is oxidized it loses electrons or negative charges; when it is reduced it gains electrons. Thus when  $Fe^{++}$  is oxidized to  $Fe^{+++}$  there is a loss of one electron. The process is therefore similar to that resulting in the loss of an electron when hydrogen passes into solution as  $H^+$ . If a platinum wire is placed in a solution containing ferrous and ferric ions, the ferrous ions tend to give up electrons to the platinum and the ferric ions tend to take them away. A difference of potential will arise depending upon the concentrations of the two ions. If an oxidizing agent is now added there will be a change of potential, slow at first and then very rapid, as the concentration of ferrous ions becomes very small compared to that of the ferric ions. This rapid change of potential marks the end point of the titration.

**Procedure.** The apparatus used is the same as for the electrometric titration of acids and bases. The platinum electrode should however be small and should not be platinized but be bright, and kept in 1:1 HCl when not in use. The calomel electrode should be connected to the negative side of the main circuit instead of the positive. Instead of a beaker a flask may be used and a current of  $CO_2$  passed over the surface of the solution (not through it) to prevent oxidation by the air.<sup>43</sup> Run in an oxidizing or reducing agent from a buret. Readings of the voltmeter are taken at intervals and at the end point a drop or two of solution produces a marked change of potential.

An electronic pH meter with the glass electrode replaced by a platinum electrode may also be used. See the manufacturer's directions for the proper connection and use.

**The Polarograph.** Instead of adding a reactant to the solution and using the change in potential at an electrode for quantitative purposes as

---

<sup>43</sup> If desired the voltmeter may be eliminated. In this case adjust the rheostat so that there is no galvanometer deflection at the beginning of the titration. The end point is indicated by the galvanometer needle being thrown off the scale.

described above, it is possible to apply an external voltage across the electrodes and electrolyze the ions by forcing them to react at the electrodes. At the cathode for example the univalent metallic ion  $M^+$  will accept an electron  $\epsilon$  and be reduced to the metallic state:

Under the proper conditions the voltage required to bring about such a reaction is characteristic of the chemical nature of the ion, and the current resulting from electron transfer may be used as a measure of the concentration of the ion.

FIG. 12. TYPICAL POLAROGRAM.

Air-free solution of 0.001 M  $CdSO_4$  in 0.1 M  $CoCl_2$  buffered at pH 5.

From Müller: *J. Chem. Education*, 18, 71 (1941).

The instrument employed to apply a known and variable voltage across the electrodes, and to measure the resulting current, is called the polarograph (Heyrovsky). A simple form of polarograph which can be assembled from equipment available in most laboratories has been described by Müller<sup>44</sup>. The graphical recording of the relation between applied voltage and current is called a polarogram (Fig. 12). Most commercial polarographs<sup>45</sup> provide for the continuous and automatic recording of the polarogram, using automatic recorders or photography.

In its simplest form, the current-voltage curve for a particular ion is approximately symmetrical around the half-wave potential, which is determined by the kind of ion undergoing reduction. Under the proper conditions the wave height becomes a measure of the concentration of the ion. The concentration of material required for polarographic analysis is quite low, ranging from  $10^{-3}$  M to  $10^{-5}$  M under ordinary circumstances in a volume of 1 ml. or more. It is worthy of note that solutions may be re-

<sup>44</sup> Müller: *J. Chem. Education*, 18, 112 (1941).

<sup>45</sup> Manufacturers of polarographs include E. H. Sargent Co. of Chicago, Leeds and Northrup of Philadelphia, Fisher Scientific Co. of New York, American Instrument Co. of Silver Springs, Md., and others.

garded as essentially unchanged in composition after polarography, since the actual amount of electrolysis which occurs is ordinarily almost undetectable in terms of concentration.

In addition to its obvious application to the field of inorganic analysis, the polarograph is finding increasing application in organic and physiological chemistry. It has been applied for example to the determination of certain hormones and vitamins, to a differentiation between normal and pathological blood serum, and to the measurement of oxygen consumption by plant and animal cells.

**Electrical Conductance of Solutions.** The power of a solution to conduct an electrical current depends on the number of ions in the solution and the mobility of those ions. The conductance of a solution is determined by placing the solution between platinum electrodes of known area in a conductivity cell and measuring the electrical resistance of this cell in a Wheatstone-bridge arrangement; details of this procedure can be found in any standard textbook on physicochemical methods. The *conductance* is the reciprocal of the resistance, and is expressed in reciprocal ohms, or *mhos*. Special conductivity cells have been devised for biological measurements, including one type which is built into a stomach tube for studying the conductance of the gastric juice.

The conductance of most biological fluids is largely dependent upon their content of sodium, potassium, chloride, and bicarbonate ions. In the gastric juice, which contains hydrochloric acid, the hydrogen ion is important in this connection. Differences between various body fluids in electrical conductance are due chiefly to differences in the electrical mobility of the ions present, since there is relatively little variation among body fluids in total electrolyte content. Thus the specific conductance of bile at 18° is  $130 \times 10^{-4}$  reciprocal ohms, that of blood serum about  $110 \times 10^{-4}$ , and that of saliva about  $50 \times 10^{-4}$ , whereas the conductance of pure gastric juice is over  $400 \times 10^{-4}$  reciprocal ohms. In total chlorine, gastric juice is not notably higher than blood serum but it conducts a current much more readily because of the great mobility of the hydrogen ion. The ionic speed (at 18° and a potential of one volt per cm.) of the sodium ion is  $43.5 \times 10^{-5}$  cm. per second, of the potassium ion  $64.6 \times 10^{-5}$ , of the chloride ion  $65.5 \times 10^{-5}$ , whereas that of the hydrogen ion is  $318 \times 10^{-5}$  cm. per second. Conductivity determinations have been used for a variety of biological purposes, as for the measurement of the volume of red cells in blood (the plasma conducts, but the red cells do not) and for other studies on blood and urine. Studies on suspensions of other types of cells also throw light on the conductivity of protoplasm and the permeability of the cells for ions.

## 2

# Carbohydrates

**Definition.** The name carbohydrates is given to a class of substances which are especially prominent constituents of plants and are found also in the animal body, either free or as components of certain proteins, lipides, and other compounds. They are called carbohydrates because they contain the elements C, H, and O, the H and O being present in the proportion to form water. The term is not strictly appropriate inasmuch as there are compounds (such as acetic acid, lactic acid, and inositol) which have H and O present in the proportion to form water, but which are not carbohydrates, and there are also true carbohydrates which do not have H and O present in this proportion—e.g., rhamnose,  $C_6H_{12}O_5$ . Chemically considered the carbohydrates are aldehyde or ketone derivatives of polyhydric alcohols, or condensation products of such substances. The aldehyde derivatives are spoken of as aldoses, and the ketone derivatives are spoken of as ketoses. It is worthy of note that among pure organic compounds, the one prepared in the largest quantity in the United States is sucrose, a carbohydrate.

**Classification.** The carbohydrates are usually classified, according to the number of simple carbohydrate groups which they contain, as mono-, di-, tri-, and polysaccharides. The monosaccharides, which contain only a single such group and cannot therefore be hydrolyzed into simpler substances, are further characterized according to the length of the carbon chain as trioses ( $C_3H_6O_3$ ), tetroses ( $C_4H_8O_4$ ), pentoses ( $C_5H_{10}O_5$ ), hexoses ( $C_6H_{12}O_6$ ), etc. The disaccharides give two molecules of simple sugars on hydrolysis and the more common ones have the general formula  $C_{12}H_{22}O_{11}$ . The polysaccharides give many molecules of simple sugars on hydrolysis and the formula for the more important members of this group is  $(C_6H_{10}O_5)_x$  where  $x$  represents the number of simple sugar groups present. In a general way the solubility of the carbohydrates varies with the complexity, the more complex being the less soluble. This means simply that, as a class, the monosaccharides (hexoses) are the most soluble and the polysaccharides (starches and cellulose) are the least soluble.

The more common carbohydrates may be classified as follows:

### I. Monosaccharides.

1. Hexoses ( $C_6H_{12}O_6$ ). Glucose, fructose, galactose, mannose.
2. Pentoses ( $C_5H_{10}O_5$ ). Arabinose, xylose, ribose, rhamnose (methyl-pentose)  $C_6H_{12}O_6$ , deoxyribose ( $C_5H_{10}O_4$ ).

### II. Disaccharides ( $C_{12}H_{22}O_{11}$ ).

Maltose, lactose, sucrose, gentiobiose, isomaltose, cellobiose.

III. Trisaccharides ( $C_{18}H_{32}O_{16}$ ).

Raffinose.

IV. Polysaccharides ( $C_6H_{10}O_5$ )<sub>x</sub>.

1. Starch Group. Starch, dextrin, glycogen, inulin.

2. Cellulose Group.

(a) Cellulose.

(b) Hemicelluloses.

(1) Pentosans. Gum arabic.

(2) Hexosans. Galactans; agar-agar; dextrans; levans.

(3) Hexo-pentosans. Pectin.

**Photosynthesis.** It is interesting to note that the bulk of these highly complex carbohydrates found in nature, whose structures in many instances are as yet unknown, are synthesized by plants from such simple precursors as water and carbon dioxide. Although the mechanism of such synthesis is still obscure, it has long been recognized that the synthetic process is related to the presence of sunlight and chlorophyll or other such coloring matter in the plant.

It is generally agreed that photosynthesis occurs in two distinct phases, one involving reactions which proceed in the absence of light (*dark reaction* or *Blackman reaction*), and the other involving the presence of light and a photosensitive catalyst such as chlorophyll or other pigment. Opinions vary as to the relative contributions of these two phases to the total process; earlier views postulated that carbon dioxide utilization took place in the dark, but oxygen evolution was associated with the presence of light and chlorophyll. More recent views incline to the belief that both carbon dioxide assimilation and oxygen production are dark reactions in the sense that they do not fundamentally require light, the function of the light being to initiate and maintain the sequence of dark reactions by the photochemical decomposition of a suitable substance, possibly water itself (see below), in the presence of the photocatalyst chlorophyll or similar pigment.

The simplest possible formulation of the over-all reaction for the production of a carbohydrate such as glucose ( $C_6H_{12}O_6$ ) from carbon dioxide and water by photosynthesis is the following:

The postulated intermediate compound  $[CH_2O]$  has the elementary composition of formaldehyde, and in fact it was suggested many years ago by Baeyer that formaldehyde was indeed the intermediate in the photosynthesis of carbohydrate. Although the reaction as shown does serve to explain the observed 1:1 ratio between carbon dioxide utilization and oxygen evolution during photosynthesis, there is little positive evidence that formaldehyde or its equivalent is concerned in the processes of photosynthesis, despite the large amount of work which has been done in this connection.

Water is shown as both reactant and product, since evidence obtained

by the use of the oxygen isotope  $O^{18}$  (*heavy oxygen*; see p. 983) as a tracer indicates that the oxygen evolved during photosynthesis is derived from the water entering the reaction and not from the carbon dioxide utilized. Furthermore, the oxygen of the water that is formed is derived from the carbon dioxide. Hence the reaction is essentially a reduction, water supplying both the hydrogen required for the reduction and the oxygen which is evolved. According to this view, the role of water in the photochemical process may be visualized as follows:

The availability of carbon dioxide labeled with radioactive carbon has stimulated research into the mechanisms of carbon dioxide assimilation during photosynthesis. The results of Calvin and his associates are of particular interest in this connection. Using various green plants (grains, algae), these investigators were able to show that, following a brief period of photosynthesis in the presence of radioactive carbon dioxide, a number of compounds containing radioactive carbon could be isolated from the plant extracts and identified. *Paper chromatography* (see p. 16) proved to be of particular value in these experiments. As the period of photosynthesis was made progressively shorter, until it was reduced to a matter of only a few seconds' exposure to light, the number of different labeled compounds isolated was reduced until only one substance stood out as a major bearer of the assimilated radiocarbon; this substance is phosphoglyceric acid:

The radiocarbon is found more abundantly in the carboxyl group of the phosphoglyceric acid than in the other two carbon atoms; this leads to the belief that the first step in  $\text{CO}_2$ -uptake during photosynthesis is the condensation of  $\text{CO}_2$  with some 2-carbon precursor to form phosphoglyceric acid. The nature of this precursor is not known; the finding of the isotope label in the other two carbon atoms of phosphoglyceric acid, but to a lesser extent, indicates that the precursor is produced by some cyclic process yet to be worked out in which phosphoglyceric acid itself plays a part; a tentative cycle involving 5-carbon and 7-carbon sugars as intermediates has been proposed, but the details remain obscure.

Phosphoglyceric acid is a well-recognized intermediate in the breakdown of carbohydrate by animal tissues (see p. 275). Indeed, the student of animal biochemistry will note a striking resemblance between the reactions of plant photosynthesis thus far described and those already known for carbohydrate metabolism in animal tissues. Furthermore,  $\text{CO}_2$ -

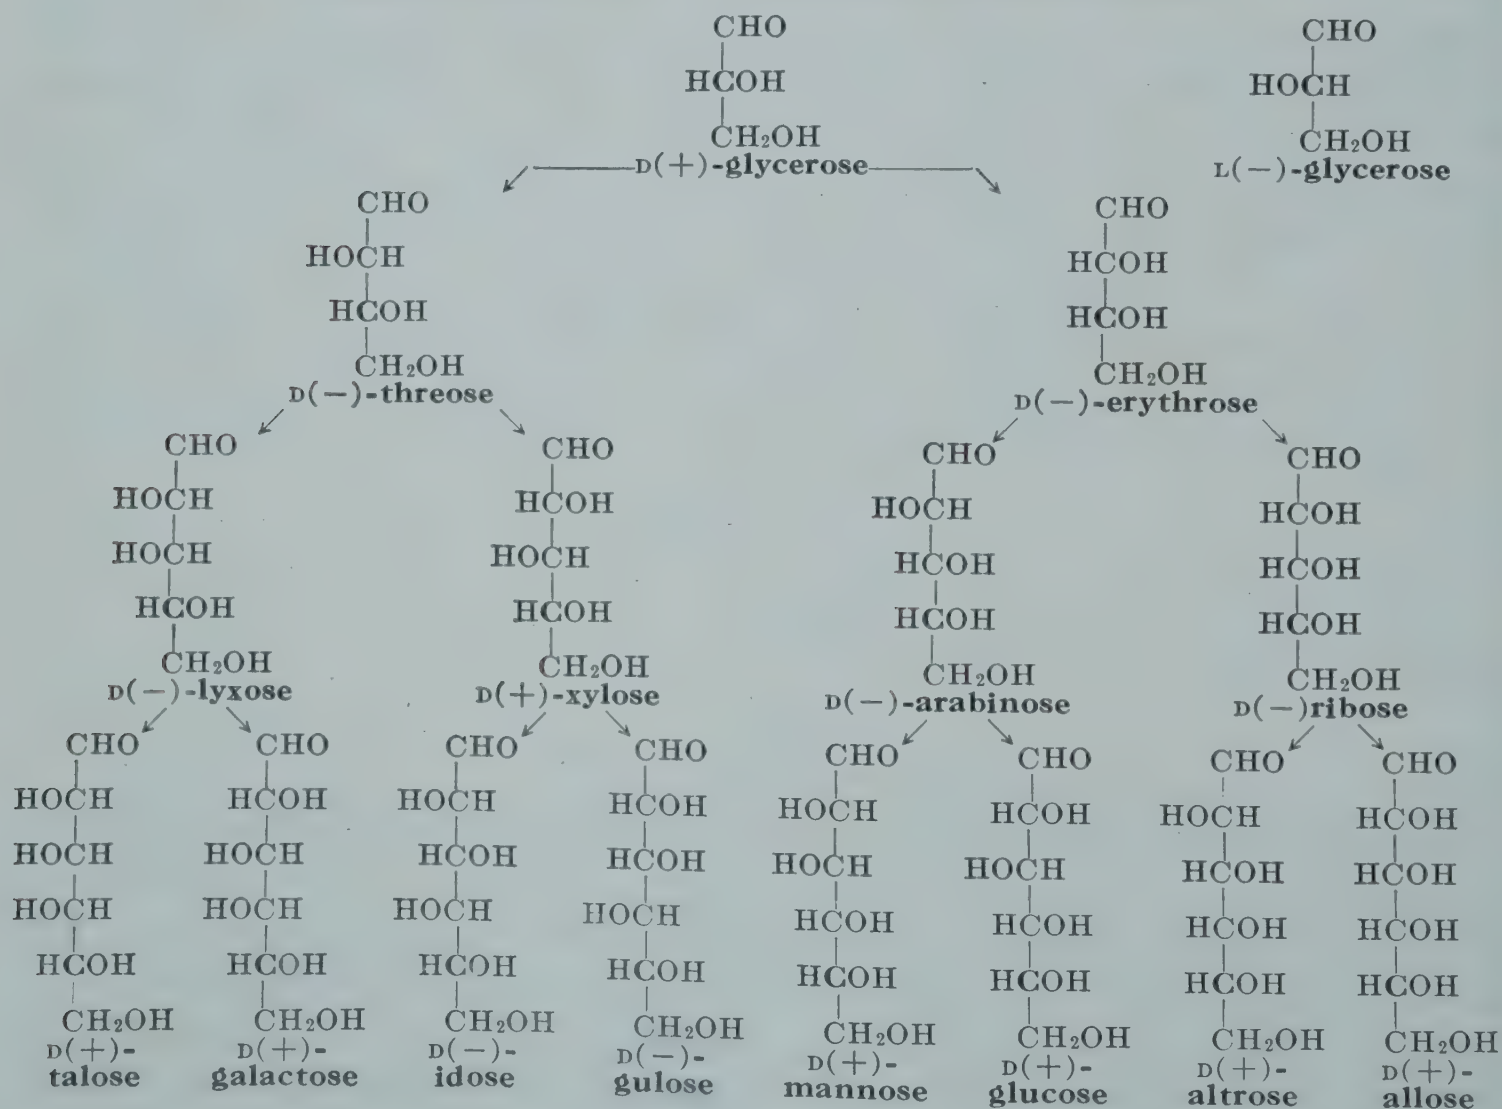

assimilation also occurs in animal tissues to a limited but definite extent, as discussed in Chapter 33, and there appears to be much in common between the processes as they occur in plants and animals. The action of light in photosynthesis remains obscure; according to one view, the light energy acts by opening the S—S bond in a compound such as 6,8-thioctic acid ( $\alpha$ -lipoic acid, see Chapter 35). This would then be the reduction reaction mentioned above; how this fits in with the water reaction remains to be established.

It should not be inferred that photosynthesis is of importance solely in connection with carbohydrates. Plants also produce nitrogenous and non-nitrogenous substances such as amino acids, proteins, and fats, which are of fundamental significance to animal nutrition, and there is no reason to believe that the energy of photosynthesis is not used directly or indirectly for the formation of these compounds also.

**Spatial Configuration of the Sugars.** The triose glycerose (also called glyceraldehyde) has one asymmetric carbon atom and therefore

#### DERIVATION OF THE D-ALDOSES FROM D-GLYCEROSE

exists in two optically active forms, one dextrorotatory and the other levorotatory. The spatial arrangement of the groups around the asymmetric carbon atom of the dextrorotatory form of glycerose is arbitrarily called the D configuration,<sup>1</sup> while that for the levorotatory form is called the L configuration. The connotation of D and L refers to spatial configuration *only* and is *not* an indication of the direction of rotation of polarized

<sup>1</sup> The carbohydrate nomenclature used in this chapter follows the recommendations of the Committee on Carbohydrate Nomenclature of the American Chemical Society.

light by the compound. If it is desired to indicate the direction of rotation for the compound, the symbols (+) meaning dextrorotatory and (−) meaning levorotatory, may be used. Thus a dextrorotatory compound with the D configuration may be indicated as D(+), while a levorotatory compound with the same configuration has the symbol D(−).

As the number of asymmetric carbon atoms in the sugar molecule increases on going from the trioses to the higher monosaccharides, the number of stereoisomers increases in accordance with the van't Hoff formula  $2^n$ , where  $n$  represents the number of asymmetric carbon atoms. All of these stereoisomers which have a configuration identical with that of D-glycrose around a suitably selected *reference asymmetric carbon atom* are called D sugars, regardless of their direction of rotation. The reference carbon atom is, for sugars containing more than one asymmetric carbon, the asymmetric carbon atom farthest removed from the active (i.e., aldehyde or ketone) end of the molecule. These relationships for the D aldoses are illustrated by the preceding chart, in which the reference asymmetric carbon atom is indicated by heavy black type. In this connection note that if the structure is written with the active group at the top it is conventional to write the OH group on the right-hand side of the reference asymmetric carbon atom for the D configuration and on the left-hand side for the L configuration. Naturally occurring sugars are mainly of the D configuration; L sugars have, however, been isolated from certain plant and animal sources.

## MONOSACCHARIDES

### HEXOSES, $C_6H_{12}O_6$

The hexoses are monosaccharides containing a chain of six carbon atoms in the molecule. They may be either aldoses or ketoses. They are among the most important of the simple sugars and occur widely distributed in nature, either in the free state or in combination with other molecules, from which they may usually be separated by hydrolysis. The most important hexoses biologically are glucose, fructose, galactose, and mannose. Of these, fructose is a ketohexose; the others are aldohexoses. The various aldohexoses differ structurally from one another solely in the spatial arrangement of the H and OH groups around certain of the carbon atoms in the molecule (see p. 58). This difference may result in markedly different physiological properties. As a class the hexoses are extremely soluble, are optically active, and possess certain characteristic general and specific chemical properties which are used in their identification and determination.

Glucose, also called dextrose or grape sugar, is found widely distributed in nature either in the free state or combined with other compounds. To-

gether with fructose, it occurs in the juice of many fruits, and is obtained commercially by the hydrolysis of starch. It is the sugar found in the blood, where its concentration normally is about 0.1 per cent. Ordinarily it is not present in the urine except possibly in traces, but appreciable amounts are found under certain conditions, such as in diabetes mellitus.

It is dextrorotatory in solution, having a specific rotation of  $+52.5^\circ$ . As an aldohexose it may be oxidized to the corresponding sugar acids or reduced to an alcohol.

Another oxidation product, glucuronic acid,  $\text{CHO} \cdot (\text{CHOH})_4 \cdot \text{COOH}$  is of considerable physiological importance, being found in the urine in combination with certain excretory products (see Chapters 20 and 29).

The behavior of glucose solutions indicates that only a small fraction of the substance is present in the free aldehyde form, the remainder existing chiefly in a less active modification in which the carbon atom of the aldehyde group is linked to the fifth carbon atom by means of an atom of oxygen. (See formulas.) This type of linkage is known as the amylenic oxide ring and since, in its formation, the first carbon atom has become asymmetric, we find that two modifications of this form exist: the first, known as  $\alpha$ -D-glucose, has a specific rotation of  $+113.4^\circ$  and the second, known as  $\beta$ -D-glucose, has a specific rotation of  $+19^\circ$ . In solution these forms are in equilibrium with each other and probably also with a small amount of the more active form having the free aldehyde group, the specific rotation of the equilibrium mixture, which is the rotation ordinarily measured, being  $+52.5^\circ$ .

In freshly prepared solutions of the usual crystalline glucose the  $\alpha$  form exists alone, the solution having a specific rotation of  $+113.4^\circ$ . On standing, however, some of the molecules are slowly transformed into the  $\beta$  form and an equilibrium is finally established between the two forms. A trace of alkali hastens the formation of this equilibrium. The specific rotation of the solution falls as the amount of the  $\beta$  form increases until equilibrium, with its characteristic specific rotation of  $+52.5^\circ$ , is reached. This phenomenon is known as *mutarotation*. Mutarotation is observed not only with glucose but with all sugars which have a free or potentially free aldehyde or ketone group in the molecule.

In addition to the amylenoxide configurations, glucose may exist in forms where the terminal carbon atom is linked through an oxygen atom to other carbon atoms than the fifth, thus forming ethylene, propylene, and butylene oxide rings each of which may exist in the  $\alpha$  and  $\beta$  forms. Of these various forms the butylene oxide form predominates, but there is evidence that all of the forms mentioned may exist in glucose solutions. These modifications are more reactive than the ordinary amylenoxide form and are presumably responsible for the concept of an "active" form of the glucose molecule, the so-called  $\gamma$ -glucose.

$\alpha$  and  $\beta$  forms, respectively, of butylene oxide structure of D-glucose

Haworth has pointed out that the amylenoxide and butylene oxide rings are structurally related to pyran and furan, respectively. Normal

glucose, using the nomenclature proposed by Haworth and now widely used, thus becomes *glucopyranose* while the butylene oxide form is called *glucofuranose*.

 $\alpha$ -D-glucopyranose $\beta$ -glucofuranose

X-ray examinations indicate that the five carbon atoms of the pyranose ring lie in the same plane while the oxygen atom lies in a different plane. The H and OH groups are placed above and below this plane of carbon atoms in accordance with the chemical evidence concerning the positions of these groups in the sugar molecule.

In common with other reducing sugars, glucose is quite labile to the action of alkali. A trace of alkali accelerates the attainment of equilibrium between the  $\alpha$  and  $\beta$  forms. Further contact with alkali results in the appearance of fructose and mannose in the solution in equilibrium with glucose, probably through the intermediate formation of a common enol tautomer involving the first two carbon atoms. Strong alkali (with heating) decomposes the molecule completely, producing a number of smaller fragments and condensation products which usually give a brown color to the solution (Moore's test, now obsolete).

Glucose is one of the sweetest of the common sugars, being excelled only by fructose and sucrose. The following table gives the relative sweetness of some of the sugars considering sucrose as 100:

| <i>Sugar</i>      | <i>Relative Sweetness</i><br>( <i>Sucrose</i> = 100) |
|-------------------|------------------------------------------------------|
| Lactose.....      | 16.0                                                 |
| Raffinose.....    | 22.6                                                 |
| Galactose.....    | 32.1                                                 |
| Rhamnose.....     | 32.5                                                 |
| Maltose.....      | 32.5                                                 |
| Xylose.....       | 40.0                                                 |
| Glucose.....      | 74.3                                                 |
| Sucrose.....      | 100.0                                                |
| Invert sugar..... | 130.0                                                |
| Fructose.....     | 173.3                                                |

## EXPERIMENTS ON GLUCOSE

The following tests are made on glucose (1 per cent solution) as a typical carbohydrate, and are *not specific for this sugar*. A specific test for glucose is the formation of glucosazone by the Phenylhydrazine Reaction (3, be-

low) without the preliminary formation of an insoluble hydrazone (mannose, p. 75) and in the absence of a positive Resorcinol-Hydrochloric Acid Reaction (fructose, p. 73).

**1. Solubility.** Test the solubility of glucose in water and in alcohol. If in doubt about the solubility of a compound, filter from excess solid and test the filtrate for the substance in question; or if the solvent is nonaqueous, allow it to evaporate and examine it for a residue.

**2.  $\alpha$ -Naphthol Reaction (Molisch).** To 5 ml. of sugar solution in a test tube, add 2 drops of Molisch's reagent (a 5 per cent solution of  $\alpha$ -naphthol in alcohol). Mix thoroughly. Incline the tube and allow about 3 ml. of concentrated sulfuric acid to flow down the side of the tube, thus forming a layer of acid beneath the sugar. A reddish-violet zone appears at the junction between the two liquids. Repeat the test, using 5 ml. of 0.1 per cent furfural solution instead of the sugar. Instead of  $\alpha$ -naphthol, 3 to 4 drops of a 5 per cent alcoholic solution of thymol may be used.<sup>2</sup>

The reaction is due to the formation of furfural and furfural derivatives, such as hydroxymethylfurfural, by the acid acting on the sugar.

The test is thus given by furfural and all furfural-yielding substances and is not a specific test for carbohydrates. Concentrated solutions of organic compounds may give a red instead of a violet color due to the charring action of the sulfuric acid. In case of doubt the reaction should be repeated on a more dilute solution of the material to be tested.

**3. Phenylhydrazine Reaction.** To a small amount of phenylhydrazine mixture (about 0.5 inch in a small test-tube),<sup>3</sup> add 5 ml. of the sugar solution, shake well, and heat on a boiling water bath for one-half to three-quarters of an hour. Allow the tube to cool slowly (not under the tap) and examine the crystals microscopically (see Plate II). Better crystals may be obtained if the tubes are allowed to cool in the water bath.

If the solution has become too concentrated in the boiling process it will be light red in color and no crystals will separate until it is diluted with water.

Yellow crystalline compounds called osazones are formed from certain sugars under these conditions, each individual sugar in general giving rise to an osazone of a definite crystalline form which is typical for that sugar. It is important to remember in this connection that, of the simple sugars of

<sup>2</sup> Thymol has the advantage that its solutions do not deteriorate. Like the  $\alpha$ -naphthol test it is also given by aldehydes and by acids such as formic, lactic, oxalic, citric, etc., and by acetone. The tests are very delicate, being given by solutions of 0.001 per cent glucose and 0.0001 per cent sucrose.

<sup>3</sup> See Appendix.

interest in physiological chemistry, glucose, fructose, and mannose yield the same osazone because of similarities in their molecular structures. Of the various osazones, it is generally possible to recognize glucosazone by its crystalline form. Maltosazone may also be recognized if it happens to crystallize in its most characteristic form. Otherwise it may not be possible to distinguish it from lactosazone. The melting points of the recrystallized osazones may be used as further means of identification, but since they extend over a range of several degrees and are not far apart for the different sugars, the determination of melting points is of doubtful value.<sup>4</sup> The reaction with glucose is sufficiently delicate to produce under favorable conditions a visible precipitate with solutions containing as little as 0.01 per cent glucose.

The reaction leading to the formation of glucosazone is indicated by the following equations. The intermediate steps between hydrazone and osazone are not known with certainty, despite earlier views to the contrary.

**4. Diffusibility of Glucose.** Test the diffusibility of glucose through a membrane, using a dialyzing bag similar to the type described under Experiments on Colloidal Solutions (see p. 10).

All monosaccharides and disaccharides are diffusible, but many polysaccharides are not.

**5. Reduction Tests.** To their free or potentially free aldehyde or ketone groups many sugars owe in part the property of readily reducing in alkaline solution the ions of certain metals such as copper, bismuth, mercury, iron, and silver. Upon this property of reduction the most widely used tests for sugars are based. For example, when blue cupric hydroxide in suspension in an alkaline liquid is heated it is converted into insoluble black cupric oxide, but if a reducing agent like certain sugars is present, the cupric hydroxide is reduced to insoluble yellow or red cuprous oxide. These changes are indicated as follows:

<sup>4</sup> See Moore and Link: *J. Biol. Chem.*, 133, 293 (1940), for a method of obtaining crystalline sugar derivatives claimed to be superior to the osazone reaction.

## PLATE II

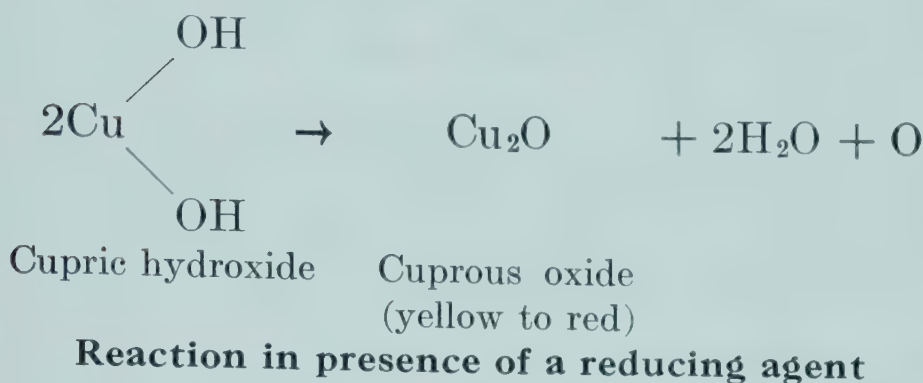

### OSAZONES.

*Upper form*, dextrosazone (glucosazone); *central form*, maltosazone; *lower form*, lactosazone.

The use of a suspension of a metallic oxide or hydroxide as a reagent is obviously impractical. Certain organic compounds, particularly those containing one or more alcoholic OH groups in the molecule (e.g., tartaric acid, citric acid, glycerol, even the sugars themselves), react in alkaline solution with metallic hydroxides to form a soluble complex ion which, though relatively little ionized, nevertheless dissociates to yield sufficient ions of the metal for reduction reactions to occur. The formation of such a complex is the basis of most of the heavy-metal reagents for reducing sugars.

The alkali in these reagents brings about considerable decomposition of the sugar molecule into reactive fragments which may also reduce the metal ions. Thus while the total reduction for a given concentration of sugar may be constant under carefully defined conditions and is therefore utilizable for quantitative purposes, it is impossible to write a balanced equation for the reaction in terms of the simple oxidation of the sugar and reduction of the metal ion.

The chemical reactions here discussed are exemplified in the following tests. (For the application of these and other tests to the detection of sugar in urine, see Chapter 29.)

**a. Fehling's Test.** To about 1 ml. of Fehling's solution<sup>5</sup> in a test tube add about 4 ml. of water, and boil. This is done to determine whether the solution will of itself cause the formation of a precipitate of brownish-red cuprous oxide. If such a precipitate forms, the Fehling's solution must not be used. To the warm Fehling's solution add sugar solution a few drops at a time and heat the mixture after each addition. The production of yellow or brownish-red cuprous oxide indicates that reduction has taken place. The differences in color of the cuprous oxide precipitates under different conditions are apparently due to differences in the size of the particles, the more finely divided precipitates having a yellow color while the coarser ones are red. In the presence of protective colloidal substances the yellow precipitate is usually formed.

<sup>5</sup> See Appendix.

In testing a solution preserved by chloroform a positive reaction may be obtained in the absence of sugar. This is due to the fact that the hot alkali produces reducing substances from the chloroform.

Ammonium salts also interfere with Fehling's test. If present in excess the solution (e.g., urine) should be made alkaline with  $\text{Na}_2\text{CO}_3$  and boiled in order to decompose the ammonium salts. Prolonged contact with hot strong alkali may lead to destruction of the sugar present.

If the solution under examination by Fehling's test is acid in reaction it must be neutralized or made alkaline before applying the test.

**5. Benedict's Test.** Benedict modified the Fehling solution to produce an improved reagent which has largely displaced the latter in routine laboratory practice. The following is the procedure for the detection of glucose in solution. To 5 ml. of the reagent<sup>6</sup> in a test tube add exactly 8 drops of the solution under examination. Mix well. Boil the mixture vigorously for two minutes (or place in boiling water for three minutes), and then allow the fluid to cool spontaneously (do not hasten cooling by immersion in cold water). In the presence of dextrose the entire body of the solution will be filled with a precipitate which may be red, yellow, or green in color, depending upon the amount of sugar present. In the presence of over 0.2 to 0.3 per cent of glucose, the precipitate will form quickly. If no glucose is present, the solution will remain perfectly clear.

Even very small quantities of glucose (0.1 per cent) yield precipitates of surprising bulk with this reagent, and the positive reaction for glucose is the filling of the entire body of the solution with a precipitate, so that the solution becomes opaque. Since *amount* rather than color of the precipitate is made the basis of this test, it may be applied, even for the detection of small quantities of glucose, as readily in artificial light as in daylight. Chloroform does not interfere with this test nor do uric acid or creatinine interfere to such an extent as in the case of Fehling's test.

**c. Bismuth Reduction Test (Nylander).** To 5 ml. of sugar solution in a test tube add one-tenth its volume of Nylander's reagent<sup>6</sup> and heat for five minutes in a boiling water bath. The solution will darken if reducing sugar is present, and upon standing for a few moments a black color will appear.

This color is due to the precipitation of metallic bismuth. If the test is made on a solution containing albumin this must be removed, by boiling and filtering, before applying the test, since with albumin a similar change of color is produced. Glucose when present to the extent of 0.08 per cent may be easily detected by this reaction. Uric acid and creatinine which interfere with the Fehling's test do not interfere with the Nylander test. It is claimed that the bismuth reduction tests give a negative reaction with solutions containing sugar when mercuric chloride or chloroform is present. The inhibitory action of mercuric chloride is questionable; the inhibitory influence of chloroform may be overcome by raising the temperature of the urine to the boiling point for a period of five minutes previous to making the test.

A positive bismuth reduction test is probably due to the following reactions:

---

<sup>6</sup> See Appendix.

*d. Barfoed's Test.* To 5 ml. of Barfoed's solution<sup>6</sup> in a test tube, add 0.5 ml. of glucose solution and heat to boiling. Reduction is indicated by the formation of a red precipitate of cuprous oxide. If the precipitate does not appear after boiling for 30 seconds, allow the tube to stand for about 15 minutes and examine.

To compare reactions of mono- and disaccharides, place 0.5-ml. portions of glucose, fructose, maltose, lactose, and sucrose solutions in each of five test tubes, add 5 ml. of Barfoed's solution to each tube, mix, and place in a boiling water bath. Note the time when signs of reduction first appear in each tube. Continue boiling for 15 minutes, remove the tubes from the bath, and note the amounts of precipitate in the bottom of each tube after it has been standing for 15 minutes. Record your observations.

Barfoed's test is *not* a specific test for glucose, serving simply to detect *monosaccharides*. Disaccharides will also respond to the test under proper conditions of acidity. Also if the sugar solution is boiled in contact with the reagent long enough to hydrolyze the disaccharide through the action of the acetic acid present in the Barfoed's solution, a positive test results. Barfoed's is a copper reduction test, but differs from Fehling's and other reduction tests in that the reduction is brought about in an acid solution. It is unsuited for the detection of sugar in urine or in any fluid containing chlorides.

*e. Tauber and Kleiner Modification of Barfoed's Test.* Introduce into one test tube 1 ml. of an approximately 0.1 per cent solution of the sugar to be tested. Put into another tube 1 ml. of water. Add 1 ml. of copper reagent<sup>7</sup> to each. Heat in a boiling water bath for 3 minutes, cool for 2 minutes. Add 1 ml. of color reagent<sup>8</sup> to each. Mix. A blue color will be obtained if monosaccharides are present. With only disaccharides present the color will be the same as in the control. Chlorides interfere but not in amounts as large as 5 mg. per ml. of solution.

*f. Picric-Acid Test.* To 5 ml. of the sugar solution add 2 to 3 ml. of saturated picric acid solution and about 1 ml. of 10 per cent  $\text{Na}_2\text{CO}_3$ . Warm. Note the development of a mahogany-red color in the presence of glucose due to reduction of the picric acid with the formation of picramic acid:

**6. Alcoholic Fermentation.** Prepare 500 ml. of a concentrated (10 per cent) solution of glucose, add a small amount of egg albumin or commercial peptone, and introduce the mixture into a liter flask. Add yeast, and by means of a bent tube connect this flask with a second flask containing a solution of barium hydroxide protected from the air by a soda-lime tube in the stopper (Fig. 13). Place the flasks in a warm place and note the passage of gas bubbles into the barium hydroxide solution. As these gas bubbles ( $\text{CO}_2$ ) enter, a white precipitate of barium carbonate will form. The glucose has been fermented

<sup>7</sup> See Appendix.

<sup>8</sup> Benedict's or Folin's phosphomolybdic reagents for sugar in blood may be used. See blood-sugar methods, Chapter 23.

according to the following equation:

The important intermediate products formed during this reaction are indicated below. (For further details see Chapter 33 on carbohydrate metabolism.)

When the activity of the yeast has practically ceased, decant the supernatant fluid, return it to the cleaned flask, connect with a condenser, and distil. Catch the first portion of the distillate, which may be redistilled if its alcohol content is low, and test for alcohol by the following reaction:

**Iodoform Test.** Render 2 to 3 ml. of the dis-

FIG. 13. FERMENTATION APPARATUS.

FIG. 14. IODOFORM.  
(Autenrieth)

tillate alkaline with sodium hydroxide solution and add a few drops of strong iodine solution—e.g., Lugol's. Warm gently and note the formation of iodoform crystals.<sup>9</sup> Examine these crystals under the microscope and compare them with those in Fig. 14.

**7. Fermentation Test.** "Rub up" in a mortar about 20 ml. of the sugar solution with a small piece of compressed yeast. Transfer the mixture to a saccharometer (Fig. 15) and put it aside in a warm place for about 12 hours. If the sugar is fermentable, alcoholic fermentation will occur and carbon dioxide will collect as a gas in the upper portion of the tube. On the completion of fermentation introduce 2 to 3 ml. of 10 per cent sodium hydroxide solution into the graduated portion by means of a bent pipet, fill the bulb portion with water, place the thumb tightly over the opening in the apparatus, and invert the saccharometer. Remembering that NaOH has the power to absorb  $\text{CO}_2$ , how do you explain the result?<sup>10</sup> Filter some of the mixture. To 5 ml. of

<sup>9</sup> The formation of iodoform may be represented by the following equations:

<sup>10</sup> The liberation of carbon dioxide by yeast is not necessarily a criterion of the presence of sugar. The presence of an enzyme, called *carboxylase*, has been demonstrated in yeast, which has the power of splitting off  $\text{CO}_2$  from the carboxyl group of amino- and other aliphatic acids.

the filtrate add several drops (enough to give a yellow color to the whole mixture), of a strong solution of iodine in potassium iodide (e.g., Lugol's). Warm gently. Note the iodoform odor and examine under a microscope for crystals of iodoform. What does a positive test here indicate?

**8. Demonstration of Optical Activity.** A demonstration of the use of the polariscope should be made by the instructor, each student being required to take readings and apply the polariscope to the determination of either the specific rotation or the concentration of a sugar.

#### THE POLARISCOPE

For a detailed description of the different forms of polariscopes, the method of manipulation, and the principles involved, the student is referred to any standard textbook of physics. A brief description follows.

Waves of ordinary light vibrate in all planes perpendicular to the direction of propagation. By certain means light may be caused to vibrate in but a single plane, and is then said to be plane polarized. Thus if a ray of light is passed through a crystal of calcite (natural crystallized calcium carbonate), it is divided into two rays (each polarized) vibrating in planes perpendicular to each other (Fig. 16). As the two rays are unequally bent it is possible to completely separate them and thus obtain light vibrating in but a single plane. For this purpose we may use a Nicol prism consisting of two pieces of calcite cemented together with Canada balsam. The ray of light *l* on entering the prism is divided into two rays. One, called the ordinary ray *o*, is

FIG. 16. PATH OF LIGHT RAY THROUGH NICOL PRISM.

reflected from the Canada balsam to the exterior and absorbed by the black varnish coating the prism. The other, the extraordinary ray *e*, passes through the balsam and emerges from the prism as polarized light. Many organic substances (sugar, proteins, etc.) have the power of twisting, or rotating, this plane of polarized light, the extent to which the plane is rotated depending upon the nature of the molecule and upon the number of molecules which the polarized light passes. Substances which possess this power are said to be *optically active*. The *specific rotation* of a substance is the rotation expressed in degrees which is afforded by 1 g. of substance dissolved in 1 ml. of water in a tube 1 decimeter in length. The specific rotation,  $(\alpha)_D$ , may be calculated by means of the following formula:

$$(\alpha)_D = \frac{\alpha}{p \cdot l}$$

FIG. 15. EINHORN SACCHAROMETER.

in which

- $D$  = sodium light,  
 $\alpha$  = observed rotation in degrees,  
 $p$  = g. of substance dissolved in 1 ml. of liquid,  
 $l$  = length of the tube in decimeters.

If the specific rotation has been determined and it is desired to ascertain the percentage of the substance in solution, this may be obtained by the use of the following formula:

$$p = \frac{\alpha}{(\alpha)_D l}$$

The value of  $p$  multiplied by 100 will be the percentage of the substance in solution.

#### SPECIFIC ROTATIONS OF MORE COMMON CARBOHYDRATES<sup>11</sup>

|                  |         |                       |         |
|------------------|---------|-----------------------|---------|
| D-Glucose.....   | + 52.5° | Sucrose.....          | + 66.5° |
| D-Fructose.....  | − 92.3° | Lactose.....          | + 52.5° |
| D-Galactose..... | + 81.5° | Maltose.....          | +137.0° |
| D-Mannose.....   | + 14.2° | Raffinose.....        | +104.0° |
| L-Arabinose..... | +104.5° | Dextrin.....          | +195.0° |
| D-Xylose.....    | + 19.0° | Starch (soluble)..... | +196.0° |
| Rhamnose.....    | + 9.0°  | Glycogen.....         | +197.0° |

An instrument by means of which the extent of the rotation may be determined is called a polariscope or polarimeter. Such an instrument designed especially for the examination of sugar solutions is termed a saccharimeter or polarizing saccharimeter. The form of polariscope in Fig. 17 consists essentially of a long barrel provided with a Nicol prism at either end (Fig. 18). The solution under examination is contained in a tube which is placed between these two prisms. At the front end of the instrument is an adjusting eyepiece for focusing and a large recording disk which registers in degrees and fractions of a degree. The light is admitted into the far end of the instrument and is polarized by passing through a Nicol prism. This polarized ray then traverses the column of liquid within the tube mentioned above and if the substance is optically active the plane of the polarized ray is rotated to the right or left. Compounds rotating the ray to the right are called dextrorotatory and those rotating it to the left levorotatory.

Within the apparatus is a disk which is so arranged as to be without lines and uniformly light at zero. Upon placing the optically active substance in position, however, the plane of polarized light is rotated or turned and it is necessary to rotate the disk through a certain number of degrees in order to secure the normal conditions—i.e., without lines and uniformly light. The difference between this reading and the *zero* is  $\alpha$ , or the observed rotation in degrees.

<sup>11</sup> The specific rotation varies with the temperature and concentration of the solution. The figures here given are for concentrations of about 10 per cent and temperatures of about 20° C. Fresh solutions may give markedly different values due to mutarotation, the figures here given representing the constant values obtained on standing.

Sugar solutions (glucose, levulose, lactose, and maltose, but not sucrose) when freshly prepared possess a changing rotation—so-called mutarotation. For this reason such solutions before polariscopic examination should be allowed to stand over night, heated to  $100^{\circ}\text{C}$ . and then cooled, or

FIG. 17. ONE FORM OF LAURENT POLARISCOPE.

treated with a drop of ammonia followed by a drop of acid. This brings about an equilibrium between the  $\alpha$  and  $\beta$  forms possessing different rotations, such as those of which ordinary glucose is a mixture.

Polarizing saccharimeters are also constructed by which the percentage of sugar in solution is determined by making an observation and multiplying the value of each division on a horizontal sliding scale by the value of

FIG. 18. DIAGRAMMATIC REPRESENTATION OF COURSE OF LIGHT THROUGH LAURENT POLARISCOPE.

The direction is reversed from that of Fig. 17. (a) Bichromate plate to purify light; (b) polarizing Nicol prism; (c) a thin quartz plate covering one-half the field and essential in producing a second polarized plane; (d) tube to contain liquid under examination; (e) analyzing Nicol prism; (f) and (g) ocular lenses.

the division expressed in terms of dextrose. This factor may vary according to the instrument.

Methods embracing the determination of the optical rotation are utilized in many analytical procedures for identifying liquids or solutions, as well as for establishing the composition of solutions.

## FRUCTOSE

As already stated, fructose, sometimes called levulose or fruit sugar, occurs widely disseminated throughout the plant kingdom in company with glucose. It has been prepared commercially from the inulin of the Jerusalem artichoke. It is not found in detectable amounts in animal tissues or fluids except under certain exceptional conditions, but in the form of its phosphoric acid esters it is a recognized intermediate in carbohydrate metabolism.

Although fructose is a ketose it nevertheless reduces metallic oxides in alkaline solution, owing to the presence in it of the terminal group  $\text{CO}\cdot\text{CH}_2\text{OH}$ . For the same reason monohydroxyacetone ( $\text{CH}_3\cdot\text{CO}\cdot\text{CH}_2\text{OH}$ ) also reduces such solutions although acetone ( $\text{CH}_3\cdot\text{CO}\cdot\text{CH}_3$ ) does not. With phenylhydrazine, fructose forms the same osazone as glucose. With methylphenylhydrazine, it forms an osazone more rapidly than does glucose.

Fructose in solution undergoes mutarotation just as glucose does, and for similar reasons, the rotation of a fresh solution being  $-133.5^\circ$  which changes to  $-92.3^\circ$  on standing or in the presence of a trace of alkali. The relation between the free ketone form and the  $\alpha$  and  $\beta$  forms, and the existence of pyranose and furanose structures, are similar to the situation already described for glucose and are illustrated by the formulas which follow:

Ordinary fructose consists chiefly of the pyranose form; fructose in the combined state, as in sucrose and inulin, appears to be invariably in the more reactive furanose form.

## EXPERIMENTS ON FRUCTOSE

1-6. Repeat Solubility, Benedict's, Phenylhydrazine, Barfoed's, Nylander's, and Fermentation tests as given for Glucose.

**7. Resorcinol-Hydrochloric Acid Reaction (Selivanoff).** To 5 ml. of Selivanoff's reagent<sup>12</sup> in a test tube add 5 drops of a fructose solution and heat the mixture to boiling. A positive reaction is indicated by the production of a red color with or without the separation of a brown-red precipitate. The latter may be dissolved in alcohol, to which it will impart a striking red color.

To compare the reactions of aldose and ketose sugars, place 0.5-ml. portions of glucose, fructose, maltose, lactose, and sucrose solutions into each of five test tubes, add 5 ml. of Selivanoff's reagent to each tube, mix, and place in a boiling water bath. Note the time when color first appears in each tube. Continue boiling for 15 minutes, noting the color developed in each tube at approximately 5-minute intervals. Record your observations.

This test is also given by sucrose which is hydrolyzed during the course of the test yielding fructose as one product. If the boiling be prolonged a similar reaction may be obtained with solutions of glucose or maltose. This has been explained in the case of glucose as due to the transformation of the glucose into fructose by the catalytic action of the hydrochloric acid. The precautions necessary for a positive test for levulose are as follows: The concentration of the hydrochloric acid must not be more than 12 per cent. The reaction (red color) and the precipitate must be observed after not more than 20 to 30 seconds' boiling. Glucose must not be present in amounts exceeding 2 per cent. The precipitate must be soluble in alcohol with a bright red color.

**8. Aminoguanidine Reaction (Tauber).**<sup>13</sup> Place 0.5 ml. of concentrated sulfuric acid in a test tube. Add 0.2 ml. of a 2.5 per cent aqueous aminoguanidine sulfate solution without mixing. Add 0.2 ml. of the test solution and mix well. In the presence of ketohexoses or compounds which yield ketohexose, a bright reddish-purple color is formed in about 1 minute and persists for several hours.

As little as 0.05 mg. of fructose is said to be detectable by this test. Sucrose and inulin also give a positive test. Aldohexose up to a concentration of 1 per cent does not interfere. Higher concentrations give a positive reaction, so solutions to be tested should be adjusted by dilution to contain not more than 0.5 — 1.0 per cent total carbohydrate. No color is given by aldopentoses, starch, glycogen, various pure proteins, or formaldehyde.

**9. Formation of Methylphenylfructosazone.** To a solution of 1.8 g. of levulose in 10 ml. of water add 4 g. of methylphenylhydrazine and enough alcohol to clarify the solution. Introduce 4 ml. of 50 per cent acetic acid and heat the mixture for 5 to 10 minutes (no longer) on a boiling water bath. On standing 5 minutes at room temperature, crystallization begins and is complete in two hours. By scratching the sides of the flask or by inoculation, the solution quickly congeals to form a thick paste of reddish-yellow silky needles. These are the crystals of methylphenylfructosazone. They may be recrystallized from hot 95 per cent alcohol (m. p. 153° C.). Glucose may give the same sazone more slowly (after five hours).

<sup>12</sup> See Appendix.

<sup>13</sup> Tauber: *J. Biol. Chem.*, 182, 605 (1950).

## GALACTOSE

Galactose occurs with glucose as one of the products of the hydrolysis of lactose. It is also found as a constituent of the galactolipides of nervous

tissue. Galactose is a typical aldohexose, is dextrorotatory and exhibits mutarotation in solution, and forms a characteristic osazone with phenylhydrazine. It ferments either very slowly or not at all with ordinary yeast, although some varieties of yeast ferment it readily. Upon oxidation with nitric acid, galactose yields mucic acid (Fig. 19), thus differentiating this monosaccharide from glucose and fructose. Lactose also yields mucic acid under these conditions. Mucic acid is  $\text{COOH}(\text{CHOH})_4\text{COOH}$ , the H and OH groups on carbon atoms 2 to 5 having the same spatial configuration as for galactose itself. Although mucic acid

FIG. 19. MUCIC ACID CRYSTALS.

From a photomicrograph furnished by Prof. William H. Welker.

contains four asymmetric carbon atoms, it is optically inactive because one half of the molecule is the mirror image of the other half (so-called *internal compensation*).

## EXPERIMENTS ON GALACTOSE

**1. Phloroglucinol—Hydrochloric Acid Reaction (Tollens).** To equal volumes of galactose solution and hydrochloric acid (sp. gr. 1.19) add a little phloroglucinol, and heat the mixture on a boiling water bath. Galactose, pentose, and glycuronic acid will be indicated by the appearance of a red color. Galactose may be differentiated from the two latter substances in that its solutions exhibit no absorption bands upon spectroscopic examination.

**2. Mucic Acid Test.**<sup>14</sup> Place about 50 mg. of galactose in a clean, dry test tube, add 1 ml. of distilled water and 1 ml. of concentrated nitric acid. Heat in a

<sup>14</sup> This modification of the mucic acid test was suggested by Dr. A. G. Cole of the Uni-

boiling water bath for  $1\frac{1}{2}$  hours. Let stand over night. A crystalline precipitate of mucic acid, which may be identified by microscopical examination of the crystals, forms under these conditions.

**3. Phenylhydrazine Reaction.** Make the test according to directions given for Glucose (p. 63).

Mannose is an aldohexose, differing structurally from glucose solely in the spatial arrangement of H and OH groups around carbon atom number 2 (see structure, p. 58). It is found in nature chiefly in the form of polysaccharides called mannans or mannosans which occur in plants, particularly in certain seeds ("vegetable ivory"), and from which mannose may be obtained by hydrolysis. Interest in mannose has been heightened by the discovery that it is present in small amount in certain animal proteins.<sup>15</sup> Mannose is a reducing sugar and is fermentable by yeast. It is readily distinguished from glucose by the formation of a sparingly soluble, colorless, crystalline phenylhydrazone when treated with phenylhydrazine at room temperature.

### EXPERIMENTS ON MANNOSE]

**1-4.** Repeat Benedict's, Barfoed's, Selivanoff's, and Fermentation tests as given for Glucose and Fructose (pp. 62, 72).

**5. Reaction with Phenylhydrazine.** Place a small amount of solid phenylhydrazine reagent in a test tube and add 5 ml. of mannose solution. Shake well and allow to stand at room temperature for 10 or 15 minutes. Observe the development of a colorless crystalline precipitate of mannose phenylhydrazone (examine a drop under the microscope). When the hydrazone has been obtained, place the tube in boiling water for one-half to three-quarters of an hour, remove, and allow to cool slowly. What change has occurred? Examine a drop of the suspension at this point under the microscope. Explain. As a control, a glucose solution may be carried through the same experimental procedure.

### PENTOSEs, $\text{C}_5\text{H}_{10}\text{O}_5$

Pentoses are usually defined as sugars containing five carbon atoms in the molecule, although rhamnose,  $\text{C}_6\text{H}_{12}\text{O}_5$ , a methylpentose, is an exception to this statement. The pentoses are widely distributed in plant and animal tissues, usually as components of some larger molecule. In plants, and more particularly in certain gums, pentoses occur as complex poly-

versity of Illinois College of Medicine. Smaller quantities of galactose (or lactose) may be used (20 mg.), but in such cases crystallization may take two or three days.

<sup>15</sup> Rimington: *Biochem. J.*, 23, 430 (1929); Sørensen and Hangard: *Compt. rend. trav. lab. Carlsberg*, 19, No. 12 (1933).

saccharides called pentosans, from which the free pentose (e.g., arabinose, xylose) may be obtained on acid hydrolysis. In both plant and animal tissues certain pentoses (ribose, deoxyribose) are universally found as constituents of the nucleoproteins of the cell, being present in the nucleic acid portion of the molecule. Ribose is likewise an essential component of certain mono- and dinucleotides found in cells, such as adenylic acid, coenzymes I and II, and riboflavin (vitamin B<sub>2</sub>).

As a class the pentoses may be either aldoses or ketoses, are nonfermentable by yeast, have strong reducing power, and form osazones with phenylhydrazine. The stereochemistry of the pentoses is similar to that already described for the hexoses. The pyranose ring appears to be the most common for the free sugars. In nucleic acids, ribose is present in the furanose form. For structures of the various aldopentoses, see p. 58. On distillation with strong hydrochloric acid, pentoses and pentosans yield furfural, a reaction which is used not only for the quantitative determination of pentoses but also in the commercial production of furfural from plant by-products such as oat hulls.

Pentoses are an important constituent of the diet of herbivorous animals. Their role in human nutrition is not well established. In the rare and apparently harmless condition known as pentosuria (p. 844) significant amounts of the pentose xyloketose are found in the urine and may lead to a false diagnosis of diabetes mellitus. Pentosuria is also said to occur in normal individuals after the ingestion of large amounts of certain fruits.

The following experiments on pentoses may be carried out on L(+)-arabinose as a typical aldopentose. The L-arabinose may be obtained from gum arabic or from plum or cherry gum by boiling for 10 minutes with concentrated hydrochloric acid.

## EXPERIMENTS ON PENTOSE

**1. Benzidine Reaction (Tauber).<sup>16</sup>** To 0.5 ml. of a 4 per cent solution of benzidine in glacial acetic acid in a test tube add 1 drop of pentose solution. Heat to boiling for several minutes and then cool immediately in cold water. The presence of pentose is indicated by the immediate appearance of a pink to red color. It is said that aldopentoses, but not ketopentoses, respond to this test.

In the authors' experience, this is much the best test for aldopentoses (for other tests and the application to urine, see p. 845. The benzidine reagent is stable for about four days. The common hexoses do not interfere. Substances containing pentose in the molecule, such as the various nucleotides, will give a positive test, but pentosans do not because they are not hydrolyzed under the conditions of the test.

**2. Phenylhydrazine Reaction.** Make this test on the pentose solution as described for glucose. For illustration of pentosazone crystals, see p. 844.

## GLYCOSIDES

Practically all the carbohydrates or carbohydrate-containing compounds found in nature which are more complex than the simple sugars

<sup>16</sup> Tauber: *Proc. Soc. Exptl. Biol. Med.*, 37, 600 (1937).

just described may be considered to be derivatives of these sugars of the type known generally as glycosides. If the sugar is glucose, the compound is known specifically as a glucoside; if galactose, a galactoside, and so on. The di-, tri-, and polysaccharides are glycosides, as well as a wide variety of naturally occurring substances such as phlorizin, salicin, amygdalin, digitalin, etc., which contain in addition to a sugar residue a specific non-sugar portion which is known as the *aglycone*.

Glycoside formation may be illustrated by the reaction between glucose and methyl alcohol, in which under the proper conditions a molecule of water is split off between an OH group in the glucose molecule and the OH of the methyl alcohol, to give a methyl glucoside:

Since the reaction involves the OH group on carbon number 1 of the glucose molecule, two methyl glucosides are possible as shown, corresponding to the  $\alpha$  and  $\beta$  forms of the glucose molecule, and in general both  $\alpha$  and  $\beta$  glycosides are found in nature. They may be readily distinguished by the use of enzymes which catalyze the hydrolytic splitting of either the  $\alpha$  or  $\beta$  glycoside linkage specifically. For example, in the presence of the enzyme maltase, only  $\alpha$  glycosides are hydrolyzed, whereas the enzyme emulsin behaves similarly with respect to  $\beta$  glycosides. In the presence of acids both types of glycosides are readily hydrolyzed to yield their component molecules.

## DISACCHARIDES

The disaccharides may be regarded as glycosides in which both components of the molecule are sugars. The common disaccharides have the general formula  $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ , and yield hexoses on hydrolysis, a molecule of water being taken up in the reaction:

The products of hydrolysis of the more common disaccharides are as follows:

In the formation of a glycoside linkage between two hexoses, the reducing property of one hexose is ordinarily lost. If the reducing property of the second hexose is not involved the resulting disaccharide is a reducing

sugar and exhibits the general properties of such a substance (e.g., osazone formation, mutarotation, etc.). Maltose and lactose are examples of reducing disaccharides. In sucrose, however, the glycoside linkage involves the potential reducing group of both the glucose and fructose components. Sucrose therefore is not a reducing sugar, does not form osazones, and does not show mutarotation in solution.

### MALTOSE, $C_{12}H_{22}O_{11}$

Maltose or malt sugar is formed in the hydrolysis of starch through the action of an enzyme, vegetable amylase (diastase), contained in sprouting barley or malt. Certain enzymes in the saliva and in the pancreatic juice cause a similar hydrolysis. Maltose is also an intermediate product of the action of dilute mineral acids upon starch. It is strongly dextrorotatory, shows mutarotation, reduces metallic ions in alkaline solution, and is fermentable by yeast after being converted to glucose by the enzyme maltase of the yeast. In common with the other disaccharides maltose may be hydrolyzed by dilute acid with the formation of two molecules of monosaccharide. In this instance the products are two molecules of glucose. With phenylhydrazine maltose forms an osazone, maltosazone. The following formula represents the probable structure of maltose.

Maltose ( $\alpha$  form)  
D-glucose 4-( $\alpha$ -D-glucoside)

As its chemical name indicates, maltose is a glucose  $\alpha$ -glucoside with a 1,4 linkage. Other disaccharides yielding only glucose on hydrolysis are known, differing from maltose in the type and position of the glucoside bond. Thus cellobiose, a glucose  $\beta$ -glucoside with a 1,4 linkage, is formed during the partial hydrolysis of cellulose. Gentiobiose, a rare disaccharide obtained from the roots of *Gentiana lutea*, is a glucose  $\beta$ -glucoside with a 1,6 linkage. Trehalose, obtained from yeast, is a nonreducing glucose  $\alpha$ -glucoside with a 1,1 linkage. Isomaltose, found as a minor end product of the action of amylases upon starch, is a glucose  $\alpha$ -glucoside with a 1,6 linkage.

### EXPERIMENTS ON MALTOSE

**1-6.** Repeat Solubility, Benedict's, Nylander's, Phenylhydrazine, Fehling's, and Fermentation tests as given for Glucose, pp. 62 ff.

LACTOSE,  $C_{12}H_{22}O_{11}$ 

Lactose or milk sugar occurs ordinarily only in milk, but it has often been found in the urine of women during the period of lactation.

Lactose is a reducing disaccharide, is dextrorotatory, exhibits mutarotation in solution, and forms an osazone with phenylhydrazine. On hydrolysis it yields glucose and galactose. Chemical evidence indicates that the glycoside linkage involves carbon number 1 of the galactose molecule; lactose is therefore a galactoside. Enzymatic studies indicate that the galactoside linkage has the  $\beta$  configuration. The structure of lactose is probably as follows:

**Lactose ( $\alpha$  form)**  
**D-glucose 4-( $\beta$ -D-galactoside)**

Since lactose exhibits mutarotation, it exists in  $\alpha$  and  $\beta$  forms. The  $\alpha$  form is the commonly obtained variety although the  $\beta$  form has become commercially available. It is more soluble than the  $\alpha$  form and has been recommended for infant feeding.

Lactose is *not* fermentable by ordinary bakers' yeast. Thus when glucose and lactose are present together in solution they may be differentiated in terms of the reducing power of the solution before and after fermentation. On oxidation with nitric acid lactose yields the sparingly soluble mucic acid because of the presence of galactose in the molecule. This reaction may be used to identify lactose under the proper conditions.

In the souring of milk the *Lactobacillus acidophilus* or *Streptococcus lacticus* and certain other microorganisms bring about lactic acid fermentation by transforming the lactose of the milk into lactic acid  $CH_3\cdot CHOH\cdot COOH$ . This same reaction may occur in the alimentary canal as the result of the action of *L. acidophilus* and certain other organisms. In the preparation of kefir and koumiss the lactose of the milk undergoes alcoholic fermentation, through the action of ferments other than yeast, and at the same time lactic acid is produced.

### EXPERIMENTS ON LACTOSE

**1-6. Repeat Solubility, Benedict's, Phenylhydrazine, Barfoed's, Nylander's, and Fermentation tests as given for Glucose, pp. 62 ff.**

**7. Mucic Acid Test.** Repeat test as given for Galactose, p. 74.

SUCROSE,  $C_{12}H_{22}O_{11}$ 

Sucrose, also called saccharose or cane sugar, is one of the most important of the sugars and occurs very extensively distributed in plants, particularly in the sugar cane, sugar beet, sugar millet, and certain palms and maples.

Sucrose is dextrorotatory, and, as before mentioned, upon hydrolysis the molecule of sucrose takes on a molecule of water and breaks down into two molecules of monosaccharide. The monosaccharides formed in this instance are glucose and fructose. This is the reaction:

This hydrolysis may be produced by bacteria, enzymes, and certain weak acids. After hydrolysis the previously strongly dextrorotatory solution becomes levorotatory. This is due to the fact that the fructose molecule is more strongly levorotatory than the glucose molecule is dextrorotatory. The reaction is therefore frequently called inversion, and the mixture of glucose and fructose obtained is called invert sugar.

Sucrose does *not* reduce metallic ions in alkaline solution and forms *no* osazone with phenylhydrazine. Prolonged boiling in the presence of an *acid* phenylhydrazine solution will, however, hydrolyze the sucrose and cause the formation of glucosazone. It is not fermentable directly by yeast, but must first be inverted by the enzyme sucrase (invertase or invertin) contained in the yeast. The probable structure of sucrose may be represented by the following formula. (Note the absence of any potential ketone or aldehyde group.) Upon inversion the active form of fructose indicated in the formula is rapidly transformed to the more stable modification.

## EXPERIMENTS ON SUCROSE

1-7. Repeat Solubility, Benedict's, Nylander's, Barfoed's, Phenylhydrazine, Selivanoff's, and Fermentation tests according to the directions given for Glucose, pp. 62 ff.

8. *Inversion of Sucrose.* To 25 ml. of sucrose solution in a beaker add 5 drops of concentrated  $H_2SO_4$  and boil one minute. Cool the solution and render

neutral with saturated barium hydroxide. Filter off the precipitate of barium sulfate and upon the resulting fluid repeat the Phenylhydrazine, Benedict's, Nylander's, and Barfoed's reactions as given for Glucose, pp. 62 ff.

### TRISACCHARIDES, $C_{18}H_{32}O_{16}$

#### RAFFINOSE

This trisaccharide, also called melitose or melitriose, occurs in cotton seed, Australian manna, and in the molasses from the preparation of beet sugar. It is dextrorotatory, does not reduce Benedict's solution, and is only partly fermentable by yeast.

Raffinose may be hydrolyzed by weak acids just as the polysaccharides are hydrolyzed, the products being fructose and melibiose. Further hydrolysis of the melibiose yields glucose and galactose. Raffinose may also be hydrolyzed by the enzyme raffinase, occurring in certain bacteria and yeasts.

### POLYSACCHARIDES

The polysaccharides are complex carbohydrates of high molecular weight, either quite insoluble in water or, when soluble, forming colloidal solutions. Polysaccharides in the solid state do not ordinarily appear to be crystalline, but a few crystalline polysaccharides have been isolated and x-ray analysis indicates that certain polysaccharides (e.g., cellulose) possess a definite crystalline structure. Through the action of certain enzymes or of acids the polysaccharides may be hydrolyzed with the formation of simpler compounds which are regarded as constituent units of the polysaccharide. Some polysaccharides yield only simple sugars on hydrolysis; others yield not only sugars but various sugar derivatives such as glucuronic or galacturonic acid (known generally as the *uronic* acids), hexosamines, and even nonsugar compounds such as ethyl alcohol, sulfuric acid, etc.

The constituent units of the polysaccharide molecule appear to be arranged in the form of a long chain, either unbranched (cellulose, amylose) or branched (glycogen, amylopectin). The linkage between units is generally the 1,4 or 1,6 glycoside bond already described, with either the  $\alpha$  or  $\beta$  configuration as the case may be. Other types of linkage are known, however. As a class the polysaccharides are nonfermentable and are non-reducing except for a trace of reducing power due presumably to the free reducing group at the end of a chain. They are optically active but do not exhibit mutarotation, and are relatively stable to alkali. This latter fact is utilized for example in the separation of glycogen from tissues prior to analytical determination.

#### STARCH, $(C_6H_{10}O_5)_x$

Starch is widely distributed throughout the vegetable kingdom, occurring in grains, fruits, and tubers. It is found in cells in the form of granules, the microscopical appearance being typical for each individual starch (see p. 85). The granules differ in size according to the source and they also differ somewhat in composition. The chief constituents are known as

amylose and amylopectin, which usually exist in a proportion of about 1:3 in the granule, although some variation in this ratio may be found. Amylopectin appears to contain a small amount of phosphoric acid as a part of the molecule. An amylohemiacellulose containing silica has also been reported as present in cereal starches.

When boiled with water, starches form pastes. The starch granules may merely swell without disintegration and thus give a high viscosity to the solutions. Potato-starch granules disintegrate more easily and form less viscous solutions. If starch is ground in a ball mill, much of it disperses readily in water like soluble starch. Soluble starch is formed by the action

FIG. 20. CRYSTALLINE CORN AMYLOSE.  
(Kerr)

of dilute hydrochloric acid upon starch. It is so called because it readily forms a limpid, clear solution with hot water. The acid apparently modifies the amylopectin of the granules so that it disintegrates more completely on heating with water.

On hydrolysis with acids, starch yields glucose. The two major constituents of the starch granule, amylose and amylopectin, must differ largely, therefore, in their molecular structure. The amylose molecule appears to consist of about 300 glucose units in an unbranched chain, with a molecular weight of about 50,000. When pure, amylose is sparingly soluble in water and forms a clear solution. It gives a deep blue color with iodine, and is completely hydrolyzed to maltose by the enzyme  $\beta$ -amylase. Amylose has been obtained in the crystalline form by Kerr (Fig. 20). Amylopectin on the other hand forms opalescent solutions, gives a purple to violet color with iodine which is much less intense than in the amylose reaction, and is only partly hydrolyzed to maltose by  $\beta$ -amylase. Amylopectin appears to contain many branched glucose chains in the molecule,

each chain having about 25 glucose units, and the entire molecule having a molecular weight up to 20 times that of amylose (Fig. 21).

The linkage between glucose units in the unbranched amylose chain is the 1,4 glycoside bond described previously. The structure of a portion of such a chain is probably that indicated in the formula:

In the branched-chain structure characteristic of amylopectin, both 1,4 and 1,6 glycoside bonds are found; the 1,4 linkage forms the linear por-

○○○○○○○○ Glucose units.

— — — End of initial degradation by  $\beta$ -amylase, yielding residual-dextrin I.

( Limit of degradation produced by  $\alpha$ -glucosidase, giving dextrin II, hydrolyzable by  $\beta$ -amylase.

— · — · — End of further attack by  $\beta$ -amylase, yielding residual dextrin III.

FIG. 21. MEYER'S SCHEMATIC REPRESENTATION OF THE BRANCHED AMYLOPECTIN MOLECULE (HASSID).

Courtesy, Wallerstein Communications.

tion of a chain and branching takes place by union of a side chain through carbon atom number 1 of a terminal glucose residue of the side chain with carbon atom number 6 of a glucose residue in the main chain.

In the course of the digestion of starch by salivary or pancreatic  $\alpha$ -amylase there is first formed soluble starch (a clear solution giving a blue

color with iodine), then dextrans giving blue or red colors with iodine, next achroodextrins giving no color with iodine, and finally maltose. Some maltose is, however, formed almost from the beginning of the digestion. The amylase apparently catalyzes the hydrolytic splitting of every other glycoside bond, thus producing maltose units. The action of  $\alpha$ -amylase on the linear and branched glucose chains, amylose and amylopectin, respectively, is discussed on p. 352. In the case of acid hydrolysis the same intermediate products are formed but glucose is the end product. The hydrolysis of starch by acid is an example of the catalytic action of the hydrogen ion.

Synthetic starches have been prepared by the action of certain muscle and potato enzymes on glucose-1-phosphate, the Cori ester (see p. 333 for an experiment demonstrating such a synthesis). These synthetic starches resemble amylose in their general properties.

## EXPERIMENTS ON STARCH

**1. Preparation of Potato Starch.** Pare a raw potato, comminute it upon a fine grater, mix with water, and whip up the pulped material vigorously before straining it through cheesecloth or gauze to remove the coarse particles. The starch rapidly settles to the bottom and can be washed by repeated decantation. Allow the compact mass of starch to drain thoroughly and spread it out on a watch glass to dry in the air. If so desired this preparation may be used in the experiments which follow.

**2. Microscopical Examination.** Examine microscopically the granules of the various starches submitted and compare them with those shown in Figs. 22 to 32. The suspension of the granules in a drop of water will facilitate the microscopical examination.

**3. Solubility.** Try the solubility of one form of starch in cold water, then in hot water. If uncertain regarding the solubility, filter and test the filtrate with iodine solution as given under 5 below. The production of a blue color would indicate that the starch had been dissolved.

**4. Iodine Test.** Place a few granules of starch in one of the depressions of a porcelain test tablet and treat with a drop of a dilute solution of iodine in potassium iodide. The granules are colored blue owing to the formation of a starch-iodine complex.

**5. Iodine Test on Starch Solution.** Place 2 to 3 ml. of dilute starch solution<sup>17</sup> in a test tube, add a drop of the dilute iodine solution, and observe the production of a blue color. Heat the tube and note the disappearance of the color. It reappears on cooling.

In similar tests note the influence of alcohol and of alkali upon the reaction between starch and iodine.

The composition of the blue-colored substance is not well defined. It appears to be an adsorption complex of starch and iodine rather than a definite compound. In performing this test the solution must always be neutral or acid in reaction.

FIGS. 22-32. STARCH GRANULES FROM VARIOUS SOURCES,  
(Leffmann and Beam)

6. *Benedict's Test.* On starch solution<sup>17</sup> (see p. 66). Does starch have any detectable reducing ability?

7. *Hydrolysis of Starch.* Place about 25 ml. of 1 per cent starch solution<sup>17</sup> in a small beaker, add 10 drops of concentrated HCl, and boil gently. By means of a small pipet, at the end of each minute remove a drop of the solution to the test tablet and make the regular iodine test. At the end of the same 1-minute intervals add exactly 3 drops of the mixture to 5-ml. portions of Benedict's solution in a series of test tubes. As the testing proceeds the reaction with iodine should become weaker and finally be negative. At this point place all the tubes containing Benedict's solution in a boiling water bath for 3 minutes, then remove and allow to cool. Note the degree of reduction in each case and compare with the rate of disappearance of the iodine reaction. Make the phenylhydrazine test upon some of the hydrolyzed starch. What sugar has been formed?

8. *Diffusibility of Starch Paste.* Test the diffusibility of starch through a suitable dialyzing membrane. Compare with glucose in this respect.

### INULIN, $(C_6H_{10}O_5)_x$

Inulin is a polysaccharide which may be obtained as a white, odorless, tasteless powder from the tubers of the artichoke, elecampane, or dahlia. It has also been prepared from the roots of chicory, dandelion, and burdock. The rubber-producing plant guayule also contains inulin. It is very slightly soluble in cold water and quite easily soluble in hot water. In cold alcohol of 60 per cent or over it is practically insoluble. Inulin gives a negative reaction with iodine solution. It is very difficult to prepare inulin which does not reduce Benedict's solution slightly. This reducing power may be due to an impurity. Practically all commercial preparations of inulin possess considerable reducing power. Inulin is a polymerized form of fructofuranose, containing about 30 fructofuranose units per chain, united by 1,2 linkages.

Inulin is levorotatory and upon hydrolysis by acids or by the enzyme inulase it yields the monosaccharide fructose which readily reduces Benedict's solution. The preparation of fructose by hydrolysis of the inulin of the Jerusalem artichoke has become of commercial importance. The ordinary amylolytic enzymes occurring in the animal body do not digest inulin. A small part of the ingested inulin may be hydrolyzed by the acid gastric juice, but the value of inulin as a significant source of energy in human dietaries must be questioned. Rats may form some glycogen from inulin. Inulin administered intravenously is readily excreted by the kidneys, apparently because the inulin molecule, though colloidal, is sufficiently small to pass through the renal glomerular membrane. Use is made clinically of this property in the *inulin clearance test* of kidney function and in other studies of renal physiology.

## EXPERIMENTS ON INULIN

1. *Solubility.* Try the solubility of inulin powder in hot and cold water and alcohol. If uncertain regarding the solubility, filter and test the filtrate with the Resorcinol-Hydrochloric acid (Selivanoff) test (see below).

2. *Iodine Test.* (a) Place 2 to 3 ml. of the inulin solution in a test tube and add a drop of dilute iodine solution. Compare with a control containing water instead of inulin solution. What do you observe?

(b) Place a small amount of inulin powder in one of the depressions of a test tablet and add a drop of dilute iodine solution. Is the effect any different from that observed above?

3. *Resorcinol-Hydrochloric Acid Test.* Test a portion of inulin solution by this test, following the directions given on p. 73. Explain the results.

4. *Benedict's Test.* Make this test on the inulin solution according to the instructions given for Glucose (p. 66). Is there any reduction? Explain.

5. *Hydrolysis of Inulin.* Place 5 ml. of inulin solution in a test tube, add a drop of concentrated hydrochloric acid, and boil for one minute. Now cool the solution, neutralize it with concentrated sodium carbonate solution, and test the reducing action of 1 ml. of the solution upon 1 ml. of Benedict's solution. Compare with a control using 1 ml. of unhydrolyzed inulin solution. Also try the Resorcinol-Hydrochloric Acid reaction as given on p. 73, likewise comparing with a control of untreated inulin solution. Explain the results.

### GLYCOGEN, $(C_6H_{10}O_5)_x$

Glycogen is the form in which carbohydrate is stored in the animal organism. It is found in the liver, muscles, kidneys, and other tissues, but is

FIG. 33. STRUCTURE OF GLYCOGEN.

The circles represent glucose units; (A) the aldehydic end of a chain.

Meyer: *Advances in Enzymology*, 3, 109, 1943.

notably absent from brain. On hydrolysis with amylase it yields maltose, and with acid it yields glucose. It thus resembles starch and the dextrans in these respects but differs significantly from these compounds in molecular architecture. In the glycogen molecule the component glucose residues are linked in chains by both 1,4- and 1,6-  $\alpha$ -glycoside bonds as with the starches, to give a highly branched structure as contrasted with the unbranched amylose or slightly branched amylopectin chains of starch (see Fig. 33). Glycogen is soluble in cold water to form an opalescent solution and ordinarily gives a red color with iodine, although some forms of

glycogen which give blue or purple colors with iodine are known. These color differences are apparently related to the extent of chain branching, the blue color representing relatively unbranched chains and the red color with iodine corresponding to highly branched chains.

For a further discussion of glycogen, and experiments, see pp. 272 and 280.

### DEXTRIN, $(C_6H_{10}O_5)_x$

The dextrins are found as intermediate products in the course of hydrolysis of starch to glucose or maltose by acids or enzymes. They are colloidal in nature but of a lower degree of molecular complexity than starch. As would be expected, a variety of dextrins are known, most of which are relatively ill-defined, the higher dextrins resembling starch in certain respects while the lower dextrins more nearly resemble the sugars. As a class the dextrins are readily soluble in water, insoluble in alcohol, and do not diffuse through cellulose membranes of ordinary porosity.

The dextrins may be hydrolyzed by dilute acids to form glucose and by amylases to form maltose. They are not fermentable by yeast. Various dextrins give different colors with iodine, depending apparently upon their molecular complexity: the higher dextrins give a blue or purple color, intermediate dextrins give a red color, and the lower dextrins may give no color at all. As is the case with most other polysaccharides, the glucose chains in the dextrin molecule have a free reducing group at one end; the ability of dextrins to reduce Benedict's solution therefore depends upon the molecular weight and chain organization, dextrins with low molecular weight showing detectable reducing power. The reducing ability of commercial dextrin preparations is ordinarily due to the presence of free sugar. The formation of various dextrins as intermediate products of the action of amylases upon starch is illustrated schematically in Fig. 21.

## EXPERIMENTS ON DEXTRIN

**1. Solubility.** Test the solubility of pulverized dextrin in hot and cold water. Dextrin forms a clear solution in water, and is thus distinguished from glycogen, which gives an opalescent solution.

**2. Iodine Test.** Place a drop of dextrin solution in one of the depressions of the test tablet and add a dilute solution of iodine in potassium iodide. A red, blue, or purple color results, depending upon the type of dextrin present. Ordinary dextrin preparations may contain some starch, and in the presence of starch it is necessary to have an excess of iodine present. If the reaction is not sufficiently pronounced, make a stronger solution from pulverized dextrin and repeat the test. The solution should be slightly acid to secure the best results.

Make proper tests to show that the red color is influenced by heat, alkali, and alcohol like the blue color given by starch (see p. 84).

The color in the case of dextrin does not reappear as readily on cooling as in the case of starch.

**3. To Detect Dextrin in Presence of Starch.** Treat 5 ml. of dextrin solution with about 10 drops of 1 per cent starch solution. To the mixture add an equal

bulk of saturated ammonium sulfate, shake vigorously, and allow to stand for five minutes. The starch is precipitated. Filter through a dry paper, and to a portion of the filtrate add a drop or two of iodine solution. Compare with an iodine test on the dextrin solution alone which has been treated with ammonium sulfate in like manner.

4. *Benedict's Test.* See if the dextrin solution will reduce Benedict's solution.

5. *Precipitation by Alcohol.* To about 50 ml. of 95 per cent alcohol in a small beaker add about 10 ml. of a concentrated dextrin solution. Dextrin is thrown out of solution as a gummy white precipitate.

6. *Diffusibility of Dextrin.* (See Starch, 8, p. 86.)

Cellulose forms a large portion of the cell walls of plants. Physically, cellulose is distinguished from other carbohydrates largely by its extreme insolubility in most of the ordinary solvents. Chemically, cellulose has been shown to consist of a large number of  $\beta$ -glucose units joined together in a chain by 1,4-glycoside bonds, as indicated in the formula given herewith. Various methods for estimating the number of glucose units in the cellulose

molecule yield results which vary from 200 to 2,000 such units, depending upon the method employed. X-ray studies of cellulose indicate that it is crystalline in structure and consists of bundles of long chains with the chains running parallel to the fiber axis. These chains are unbranched and straight rather than coiled, and there is some evidence for the existence of cross linkages between adjacent chains; the chemical nature of such cross linkages is obscure. The close packing of the long straight chains produces a fiber with much mechanical strength, and may also account for the insolubility of cellulose.

Cellulose is not soluble in water or the usual organic solvents nor in dilute acid or alkali. It is soluble however in a variety of special solvents, such as Schweitzer's reagent (ammoniacal copper hydroxide), zinc chloride—hydrochloric acid solution, and sodium hydroxide and  $\text{CS}_2$ , which latter are the reagents for making viscose, a form of artificial silk. With 10 per cent sodium hydroxide, cellulose is converted into *hydrocellulose* and is said to be mercerized. About 70 per cent sulfuric acid converts it into *vegetable parchment*. Such commercial products as rayon, cellophane, sausage casing, etc., are made from cellulose. With strong nitric acid and concentrated sulfuric acid it forms nitrocellulose.

Cellulose is not hydrolyzed by boiling with dilute mineral acids. It may

be hydrolyzed, however, by treating with concentrated sulfuric acid, then diluting the solution with water, and boiling. The product of this hydrolysis is glucose. Hydrolysis of cellulose by certain bacteria has been reported to yield the disaccharide cellobiose, analogous to the production of maltose from starch.

There is some difference of opinion as to the exact extent to which cellulose is utilized in the animal organism. It is no doubt more efficiently utilized by herbivora than by carnivora or by man. It is claimed that about 25 per cent may be utilized by herbivora and less than 5 per cent by dogs, whereas the quantity utilized by man is too small for it to play a nutritional role in the diet of a normal individual. In neither man nor the lower animals has there been demonstrated any formation of sugar or glycogen from cellulose. It is probable that the cellulose which disappears from the intestine is transformed for the most part into lower fatty acids (acetic, etc.) by the action of intestinal bacteria. A *cellulase* capable of digesting sawdust and filter paper has been found in the digestive diverticula attached to the stomach of the shipworm.

## EXPERIMENTS ON CELLULOSE

For these experiments, a high-grade filter paper, absorbent cotton, or cleansing tissue may be used.

**1. Solubility.** Test the solubility of cellulose in water, dilute and concentrated acid, and alkali.

**2. Iodine Test.** Add a drop of dilute iodine solution to a few shreds of cotton on a test tablet. Cellulose differs from starch and dextrin in giving no color with iodine.

**3. Formation of Amyloid.**<sup>18</sup> To 6 ml. of distilled water in a test tube, add 10 ml. of concentrated sulfuric acid. The acid should be added to the water in small portions and the mixture stirred with a stirring rod and cooled under the tap, or by immersion in a beaker of cold water, between additions. To the cooled mixture add a two-inch square of cleansing tissue and stir for from 5 to 10 minutes, when most of the tissue is dissolved. Pour about 3 ml. of this solution into about 10 ml. of distilled water, and note the flocculent precipitate of amyloid formed. To another small portion of the solution add iodine and note the blue or black color formed. Pour the remainder of the acid solution of tissue into about 25 ml. of distilled water in a small beaker and boil for 15 to 30 minutes. Now cool, neutralize with solid sodium carbonate, and test with Benedict's solution. Glucose has been formed from the cellulose by the action of the acid.

**4. Ammoniacal Cupric Hydroxide Solubility Test (Schweitzer).** Place a 2-inch square of cleansing tissue in a test tube, add 5 ml. of Schweitzer's reagent,<sup>19</sup> and stir the cellulose with a glass rod. When completely dissolved (5 to 10 minutes), dilute with an equal volume of distilled water, and acidify the solution with acetic acid. An amorphous precipitate of cellulose is produced.

<sup>18</sup> This substance derives its name from *amylum* (starch) and is not to be confounded with amyloid, the glycoprotein.

<sup>19</sup> See Appendix.

5. *Hydrochloric Acid—Zinc Chloride Solubility Test (Cross and Bevan)*. Place a little absorbent cotton in a test tube, add Cross and Bevan's reagent,<sup>19</sup> and stir the cellulose with a glass rod. When solution is complete, reprecipitate the cellulose with 95 per cent alcohol.

6. *Iodine—Zinc Chloride Reaction*. Place a little absorbent cotton or quantitative filter paper in a test tube and treat it with the iodine—zinc chloride reagent.<sup>19</sup> A blue color forms on standing. Amyloid has been formed from the cellulose through the action of the  $\text{ZnCl}_2$  and the iodine solution has stained the amyloid blue.

7. *Other Cellulose Solvents*. It has been demonstrated by Deming that there are many excellent solvents for cellulose (filter paper)—for example, the concentrated aqueous solutions of certain salts such as (1) antimony trichloride, (2) stannous chloride, and (3) zinc bromide. In hydrochloric acid solution the solvent action of the above salts is increased. The following salts are also good solvents in hydrochloric acid solution: mercuric chloride, bismuth chloride, antimony pentachloride, tin tetrachloride, and titanium tetrachloride. In the case of the last-mentioned salt the swollen, transparent character of the cellulose fibers preliminary to solution can be seen very nicely.

Try selected solvents suggested by the instructor.

### HEMICELLULOSES

The hemicelluloses differ from cellulose in that they may be hydrolyzed upon boiling with dilute mineral acids. They differ from other polysaccharides in being not readily digested by amylases. Upon hydrolysis hemicellulose may yield pentoses or hexoses or both, together with uronic acids. The vegetable gums and pectins may be included under this head.

**Pentosans.** Pentosans yield pentoses upon hydrolysis. So far as is known they do not occur in the animal kingdom. They have, however, a very wide distribution in the vegetable kingdom, being present in leaves, roots, seeds, and stems of all forms of plants, many times in intimate association or even chemical combination with galactans and uronic acids. In herbivora, pentosans are 40 to 80 per cent utilized. The few tests on record as to the pentosan utilization by man indicate that 80 to 95 per cent disappears from the intestine. According to Cramer, bacteria are efficient hemicellulose transformers. It has not yet been demonstrated that pentosans form glycogen in man, and for this reason they must be considered to play an unimportant part in human nutrition. Gum arabic, an important pentosan, may be hydrolyzed by boiling with strong hydrochloric acid for a short time. The pentose arabinose results from such hydrolysis.

**Galactans.** In common with the pentosans the galactans have a very wide distribution in the vegetable kingdom. One of the most important members of the galactan group is agar-agar, a product prepared from certain types of Asiatic or American seaweed. Chemically, the agar molecule appears to consist of a chain of D-galactose units linked by a 1,3-glycoside bond, with a single L-galactose unit in a 1,4 linkage at the reducing end of the chain, this latter unit also being esterified in the 6 position with sulfuric acid. Thus the products of hydrolysis include much D-galactose, some L-galactose, and sulfuric acid. This galactan is about 50

per cent utilizable by herbivora and 8 to 27 per cent utilizable by man. Agar ingestion has been shown to be a very efficient therapeutic aid in cases of chronic constipation. This is particularly true when the constipation is due to the formation of dry, hard fecal masses (scybala), a type of fecal formation which frequently follows the ingestion of a diet which is very thoroughly digested and absorbed. The agar, because of its relative indigestibility and its property of absorbing water, yields a bulky fecal mass which is sufficiently soft to permit of easy evacuation. Agar has been used with good results in the treatment of constipation in children. Agar is not limited to its use in connection with constipation, but may serve in other capacities as an aid to intestinal therapeutics.

**Dextrans and Levans.** The dextrans are polysaccharides produced by the action of certain bacteria on sucrose, the reaction being as follows:

In effect, the fructose residue is removed from the sucrose molecule, and the remaining glucose residues polymerized to form the polysaccharide dextran. The dextrans have a high molecular weight (which varies with the conditions of preparation and species of organism used) and form rather viscous colloidal solutions in water. For many years they were regarded as undesirable by-products in the sugar and fermentation industries. They have attracted considerable clinical interest because of their proposed use as plasma substitutes, since they form nontoxic solutions with a high colloidal osmotic pressure, suitable for intravenous administration as a temporary replacement for plasma proteins lost from the blood by hemorrhage. Dextrans so administered gradually disappear from the circulation; their metabolic fate is however still obscure.

The dextrans consist almost entirely of D-glucose units joined in chains by 1,6-glycoside bonds, with evidence for occasional cross-linking between chains by the formation of 1,4 bonds. On hydrolysis with dilute acids, dextrans yield only D-glucose. In general, dextrans are not acted upon by ordinary amylases, although some exceptions to this rule are known.

Similar polysaccharides containing fructose residues and known as levans are also produced by certain microorganisms. The reaction is analogous to that given for dextran formation, with the formation of glucose and polymerized fructose (levan), except that the incidence of side reactions involving the breakdown of part of the sucrose to free glucose and fructose appears to be greater. Chemically, levans are found to be polymers of fructose with 2,6 linkages between units, thus differing from inulin, which contains 1,2 linkages. Levan formation has relatively little commercial interest at the present time.

**The Pectins.** The pectins are colloidal carbohydrates which with the proper concentration of acid and of sugar form gels. For a gel to form, there must be present from 0.3 to 0.7 per cent pectin, 65 to 70 per cent of sugar (usually sucrose), and a pH of 3.2 to 3.5. Commercial pectin is prepared from apples and lemons. On hydrolysis the pectins yield galactu-

ronic acid, arabinose, galactose, acetic acid, and methyl alcohol. The characteristic properties of pectin appear related to the presence of a long chain of anhydrogalacturonide residues, partly methyl esterified. Non-galacturonide material, galactan, and araban, which appear to act chiefly as diluents, may however make up a considerable portion of the weight of the pectin.

### EXPERIMENTS ON A PENTOSAN

1. *Solubility.* Test the solubility of gum arabic in hot and cold water and alcohol.

2. *Iodine Test.* Add a drop of dilute iodine solution to a little gum arabic on a test tablet. It resembles cellulose in giving no color with iodine.

3. *Hydrolysis of Gum Arabic.* Introduce a little gum arabic into a test tube, add 5 to 10 ml. of strong hydrochloric acid (conc. HCl and water 1:1), and heat to boiling for 5 to 10 minutes. Cool, neutralize with sodium hydroxide, and test by the Benedict or some other reduction test. A positive reaction should be obtained, indicating that the gum arabic has been hydrolyzed by the acid with the production of a reducing substance. What is this reducing substance? How would you identify it?

### EXPERIMENTS ON A GALACTAN

1. *Solubility.* Test the solubility of agar-agar in hot and cold water. Observe its marked property of imbibing water (see above).

2. *Iodine Test.* Add a drop of dilute iodine solution to a little agar-agar on a test tablet. It resembles cellulose in giving no color with iodine.

3. *Hydrolysis of Agar-agar.* Introduce a few pieces of agar-agar in a test tube, add 5 to 10 ml. of strong hydrochloric acid (conc. HCl and water 1:1) and heat to boiling for 5 to 10 minutes. Cool, neutralize with sodium hydroxide, and test by the Benedict or some other reduction test. A positive reaction should be obtained, indicating that the agar-agar has been hydrolyzed by the acid with the production of a reducing substance. What is this reducing substance? How would you identify it?

### EXPERIMENTS ON PECTIN

1. *Preparation of Pectin.* Pare off the yellow layer from a grapefruit rind. Run through a meat chopper, cover with water, and let stand over night. Strain on cheesecloth and squeeze out the fluid. Boil the pulp with water for about two hours, bringing finally to a low volume. Pour off the fluid and add alcohol to precipitate the pectin. Filter and dry.

2. *Formation of a Gel.* Into a weighed 400-ml. beaker introduce 70 g. of cane sugar, 1 g. of dry pectin, 0.5 g. of citric or tartaric acid, and 100 ml. of water. Heat to boiling. Concentrate to a weight of 100 g. Let it stand over night.

### REVIEW OF CARBOHYDRATES

In order to facilitate the student's review of the carbohydrates, the preparation of a chart similar to the appended model is recommended. The signs + and - may be conveniently used to indicate positive and nega-

tive reaction. Only those carbohydrates which are of greatest importance from the standpoint of physiological chemistry have been included in the following model chart.

| <i>Carbo-<br/>hydrate</i> | <i>Solubility</i> | <i>α-Naphthol Reaction<br/>(Molisch)</i> | <i>Benedict's Test</i> | <i>Nylander Test</i> | <i>Barfoed's Test</i> | <i>Iodine Test</i> | <i>Resorcinol—Hydrochloric<br/>Acid Reaction (Selivanoff)</i> | <i>Tauber's Benzidine Test</i> | <i>Mucic Acid Test</i> | <i>Precipitation by<br/>Alcohol</i> | <i>Osazone</i> | <i>Rotation</i> | <i>Diffusibility</i> | <i>Fermentation</i> | <i>Products of Hydrolysis</i> | <i>Remarks</i> |

QUANTITATIVE DETERMINATION OF CARBOHYDRATES

See the chapters on Blood, Milk, and Urine for methods applicable also to pure solutions.

SCHEME FOR THE DETECTION OF CARBOHYDRATES

If the solution is alkaline, neutralize or make faintly acid with HCl. Test a few drops on a test tablet with iodine solution.

Blue color indicates **Starch** and possible **Dextrins**.\*

Reddish color indicates

**Dextrin** if unknown solution is clear.

If uncertain as to the differentiation between dextrin and glycogen, add ammoniacal basic lead acetate to some of the unknown solution.

**Glycogen** if unknown solution is opalescent.

No precipitate indicates **dextrin**.

Precipitate indicates **glycogen**.

Reduction indicates **glucose, fructose, mannose, galactose, pentose, maltose, lactose**, possibly along with nonreducing carbohydrates.

No reduction indicates the possible presence of **sucrose**.

To 5 ml. of the unknown solution in a test tube, add one drop of concentrated HCl and boil for one minute. Cool, neutralize with concentrated  $\text{Na}_2\text{CO}_3$  solution, and test by Benedict's test.

Test the unknown with Barfoed's solution.

If Benedict's solution is reduced, boil with excess reagent until filtrate no longer gives a reduction on further boiling. Filter, acidify filtrate with conc. HCl, boil for one minute, cool, neutralize with conc.  $\text{Na}_2\text{CO}_3$ , and test again with Benedict's solution. Reduction indicates the presence of **sucrose** in the unknown solution.

Reduction indicates **glucose, fructose, mannose, galactose, pentose**, possibly along with nonreacting carbohydrates.

No reduction indicates **lactose**, or **maltose** or both. Differentiate by osazone reaction, mucic acid test, or fermentation test.

Reduction indicates the presence of **sucrose** in the unknown solution. No reduction indicates the absence of **sucrose** in the unknown solution.

Test the unknown by reosazone—hydrochloric acid (Sullivanoff). Positive test indicates **fructose** if sucrose and inulin are absent. Sucrose if present will already have been detected. Absence of inulin is shown by lack of turbidity on treating the unknown with 3 volumes of 95 per cent alcohol.

Treat the unknown with phenylhydrazine reagent as for osazone test. Formation of colorless insoluble phenylhydrazones before heating indicates **mannose**. Heat to complete osazone reaction. Formation of yellow insoluble osazone during heating indicates **glucose, fructose, mannose**. Osazone separating out only after cooling indicates **lactose, maltose**. Examine crystals under microscope to identify various sugars.

Try mucic acid test on the unknown. Positive test indicates **lactose, galactose**. Differentiate by Barfoed test, osazone.

Try benzidine reaction (Tauber) on the unknown. Positive test indicates **pentose** or **pentosan**. Absence of pentosan is shown by lack of turbidity on treatment of unknown with 3 volumes of 95 per cent alcohol.

Rub up a portion of unknown solution with yeast, and allow to stand until fermentation is complete. Filter and test filtrate by Benedict test. Reduction before and after yeast treatment indicates **galactose, lactose, pentose**; reduction before but not after fermentation indicates **glucose, fructose, mannose, maltose**.

\* **Starches** may be precipitated from solution by addition of an equal volume of saturated ammonium sulfate solution.

† If iodine test indicates the presence of **polysaccharides** in the unknown solution, these may be precipitated from solution, before testing for the simple sugars, by the addition of 3 volumes of 95 per cent alcohol. Excess alcohol may be evaporated from the neutral filtrate.

## Fats

### THE LIPIDES

The term *lipide* is applied to a group of naturally occurring substances characterized by their insolubility in water and their solubility in such *fat solvents* as ether, chloroform, boiling alcohol, and benzene. They are limited to substances which are utilizable by the animal organism. Individual members of this group show large individual variations in solubility, but as a class the lipides are readily distinguishable from the carbohydrates and the proteins, the other two great groups of naturally occurring compounds. Chemically, the lipides are either esters of fatty acids or substances capable of forming such esters. They are very widespread in nature, being found in all vegetable and animal matter. Some members of this group, such as the phosphatides and sterols, are found in all living cells where, with the proteins and carbohydrates, they form an essential part of the colloidal complex of protoplasm. Complex lipides are also found in large quantities in brain and nervous tissues, thus indicating the important role these substances must play in the living organism. Other lipides, such as the fats and oils, represent the chief form in which excess nutrients are stored in the animal body. They arise from ingested lipides and from the metabolism of carbohydrates and proteins, and are stored in fat deposits, such as in the subcutaneous connective tissue, in the intermuscular connective tissue, in the omentum, in the perirenal fat depots, and in the genital fat. Lipides act as heat insulators and as reserve supplies of energy. They may be classified as follows:

### CLASSIFICATION

#### SIMPLE LIPIDES

The simple lipides are esters of fatty acids with certain alcohols. They are usually further classified according to the nature of the alcohols, as follows:

**1. Fats and Oils.** Esters of fatty acids and glycerol. Oils are fats which are liquid at room temperature.

**2. Waxes.** Esters of fatty acids with long-chain aliphatic alcohols or with cyclic alcohols. These may be subdivided into: (1) True waxes; (2) Cholesterol esters; (3) Vitamin A and its carotenol esters; and (4) Vitamin D esters.

## COMPOUND OR CONJUGATE LIPIDES

The compound lipides are esters of fatty acids which, on hydrolysis, yield other substances in addition to fatty acids and an alcohol. Some important members of this group are:

**1. Phospholipides (Phosphatides).** Lipides which, on hydrolysis, yield fatty acids; phosphoric acid; sometimes, but not always, glycerol; and a nitrogenous base. These are subdivided into the following groups:

(a) **LECITHINS.** Lipides containing fatty acids, phosphoric acid, glycerol, and the nitrogenous base choline.

(b) **CEPHALINS.** Lipides which yield on hydrolysis fatty acids, glycerol, phosphoric acid, and either the base ethanolamine (colamine) or the amino acid serine. Lipides of uncertain structure which contain inositol, fatty acids, phosphoric acid, ethanolamine, and possibly galactose and tartaric acid are also included in this class.

(c) **SPHINGOMYELINS.** Lipides containing the nitrogenous base sphingosine, a single fatty-acid molecule, phosphoric acid, and choline, but no glycerol.

**2. Cerebrosides.** Lipides which contain carbohydrate (galactose or glucose), one fatty acid, and sphingosine, but no phosphoric acid or glycerol.

**3. Sulfolipides.** Similar to cerebrosides except that sulfuric acid is present as cerebronic acid ester. Sulfolipides containing sphingosine, galactose, cerebronic acid, sulfuric acid, and potassium have been described.<sup>1</sup>

## DERIVED LIPIDES

The derived lipides are substances formed in the hydrolysis of simple or compound lipides which still retain the properties of this class of compound.

**1. Fatty Acids.** Saturated and unsaturated acids.

**2. Alcohols.** Compounds of high molecular weight but not glycerol. These may be classified as follows:

(a) **ALIPHATIC ALCOHOLS** such as cetyl ( $\text{CH}_3(\text{CH}_2)_{14}\text{CH}_2\text{OH}$ ), stearyl ( $\text{CH}_3(\text{CH}_2)_{16}\text{CH}_2\text{OH}$ ), and myricyl ( $\text{CH}_3(\text{CH}_2)_{28}\text{CH}_2\text{OH}$ ).

(b) **STEROLS** which contain the phenanthrene nucleus (cholesterol, ergosterol, sitosterol, stigmasterol).

(c) **ALCOHOLS CONTAINING THE  $\beta$ -IONONE RING.** These include vitamin A, kitol, and carotenols such as cryptoxanthin, lutein, and zeaxanthin.

**3. Hydrocarbons.** Compounds having no carboxyl or alcohol groups, and which cannot be saponified.

(a) **ALIPHATIC HYDROCARBONS.** Pentacosane,  $\text{CH}_3(\text{CH}_2)_{23}\text{CH}_3$ , and homologues to hentriacontane,  $\text{C}_{31}\text{H}_{64}$ .

(b) **CAROTENOIDS.**  $\text{C}_{40}\text{H}_{56}$  compounds, such as  $\alpha$ -,  $\beta$ -, and  $\gamma$ -carotene and lycopene.

(c) **SQUALENE.** Unsaturated hydrocarbon,  $\text{C}_{30}\text{H}_{56}$ , in olive and shark-liver oils.

**4. Vitamins D.** Differ from steroids in that the phenanthrene nucleus is ruptured between carbons 9 and 10.

<sup>1</sup> Blix: *Z. physiol. Chem.*, **219**, 82 (1933).

5. **Vitamins E.** Chroman derivatives,  $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -tocopherols.

6. **Vitamins K.** Derivatives of 1,4-naphthoquinone with long hydrocarbon side chains.

## THE FATS

**The Fatty Acids.** The fatty acids found in fats and other lipides are of various types. Some of them, like palmitic acid ( $\text{CH}_3(\text{CH}_2)_{14}\text{COOH}$ ) and stearic acid ( $\text{CH}_3(\text{CH}_2)_{16}\text{COOH}$ ), are straight-chain saturated acids belonging to the acetic acid series, and have the general formula  $\text{C}_n\text{H}_{2n}\text{O}_2$ . Others are unsaturated and have from one to four, and even more, double bonds in their molecules. Thus oleic acid ( $\text{C}_{18}\text{H}_{34}\text{O}_2$ ) has one double bond in its molecule, linoleic acid ( $\text{C}_{18}\text{H}_{32}\text{O}_2$ ) has two double bonds, and linolenic acid ( $\text{C}_{18}\text{H}_{30}\text{O}_2$ ) has three. Practically all the fatty acids found in nature contain an even number of carbon atoms, although porpoise oil and the head oil of the white whale have been shown to contain isovaleric acid ( $\text{C}_5\text{H}_{10}\text{O}_2$ ). In addition to the above types of acid, some lipides contain hydroxy acids, both saturated and unsaturated, and dicarboxylic acids. Thus castor oil contains an unsaturated hydroxy acid, ricinoleic acid ( $\text{C}_{18}\text{H}_{34}\text{O}_3$ ). Certain cyclic saturated and unsaturated fatty acids are likewise found in nature. Some of the more important chemical and physical properties of saturated and unsaturated fatty acids are discussed below.

### SATURATED FATTY ACIDS, $\text{C}_n\text{H}_{2n}\text{O}_2$ OR $\text{C}_n\text{H}_{2n+1}\text{COOH}$

The physical properties of the saturated fatty acids depend upon their molecular weights. Whereas those fatty acids that contain ten carbon atoms or fewer in their molecules are liquids at room temperature, the remainder are solids whose melting points rise with increasing molecular weight. The liquid acids are also known as volatile fatty acids, since they may be distilled with steam, whereas the others, the nonvolatile acids, are

#### SATURATED FATTY ACIDS

| <i>Common Name</i> | <i>Chemical Name</i> | <i>Structure</i>                                     | <i>Occurrence</i>                          |
|--------------------|----------------------|------------------------------------------------------|--------------------------------------------|
| Butyric.....       | Butanoic             | $\text{CH}_3\cdot(\text{CH}_2)_2\cdot\text{COOH}$    | Butter fat                                 |
| Caproic.....       | Hexanoic             | $\text{CH}_3\cdot(\text{CH}_2)_4\cdot\text{COOH}$    | Butter fat, coconut oil                    |
| Caprylic.....      | Octanoic             | $\text{CH}_3\cdot(\text{CH}_2)_6\cdot\text{COOH}$    | Butter fat, coconut oil                    |
| Capric.....        | Decanoic             | $\text{CH}_3\cdot(\text{CH}_2)_8\cdot\text{COOH}$    | Butter fat, coconut oil                    |
| Lauric.....        | Dodecanoic           | $\text{CH}_3\cdot(\text{CH}_2)_{10}\cdot\text{COOH}$ | Laurel kernel oil, butter fat, coconut oil |
| Myristic.....      | Tetradecanoic        | $\text{CH}_3\cdot(\text{CH}_2)_{12}\cdot\text{COOH}$ | Nutmeg fat, butter fat, vegetable fats     |
| Palmitic.....      | Hexadecanoic         | $\text{CH}_3\cdot(\text{CH}_2)_{14}\cdot\text{COOH}$ | Most vegetable and animal fats             |
| Stearic.....       | Octadecanoic         | $\text{CH}_3\cdot(\text{CH}_2)_{16}\cdot\text{COOH}$ | Most vegetable and animal fats             |
| Arachidic.....     | Eicosanoic           | $\text{CH}_3\cdot(\text{CH}_2)_{18}\cdot\text{COOH}$ | Peanut oil                                 |
| Behenic.....       | Docosanoic           | $\text{CH}_3\cdot(\text{CH}_2)_{20}\cdot\text{COOH}$ | Rapeseed oil, peanut oil                   |
| Lignoceric....     | Tetracosanoic        | $\text{CH}_3\cdot(\text{CH}_2)_{22}\cdot\text{COOH}$ | Cerebrosides, sphingomyelin, peanut oil    |

carried over by steam distillation only in traces or not at all. Fatty acids with four carbon atoms or fewer are miscible with water in all proportions. As the length of the carbon chain increases beyond this, however, the solubility rapidly diminishes to zero. The common straight-chain saturated fatty acids found in nature as constituents of lipide molecules are listed in the table on p. 99.

### UNSATURATED FATTY ACIDS

The unsaturated fatty acids are characterized by the presence of one or more double bonds in the molecule. They have been classified in accordance with the number of double bonds as monoethenoid, diethenoid, triethenoid, etc., and named by reference to the parent hydrocarbon, the position of the double bond or bonds in the chain being indicated by a number referred to the carboxyl carbon atom as number one. As is true of the saturated fatty acids, many of the unsaturated fatty acids have common names which may be used as frequently as the chemical name.

Because of the presence of the double bond the unsaturated fatty acids are much more reactive than the saturated acids, the reactivity increasing with increase in the number of double bonds. The unsaturated fatty acids are capable of taking up one molecule of water, oxygen, hydrogen, bromine, or iodine at each double bond, and the amount of such substance (e.g., iodine) absorbed by a given weight of acid is used to determine its degree of unsaturation. It is obvious that a variety of isomerism is possible among the unsaturated fatty acids, depending not only on the position of the double bond in the chain but also on *cis-trans* isomerism across a double bond. Relatively few of the large number of possible isomers of the unsaturated fatty acids are found in nature.

The most common unsaturated fatty acid found in nature is the monoethenoid acid oleic acid (9-octadecenoic acid). This acid is so widely distributed that, according to Hilditch, no natural fat or phosphatide has as yet been found not to contain oleic acid. Vaccenic acid, an isomer of oleic acid, has received considerable attention. It occurs in low concentration in certain animal and vegetable tissues. Other common unsaturated fatty acids include (1) the diethenoid acid linoleic acid, found in both animal and plant fats; (2) linolenic acid, which is a triethenoid acid found largely in vegetable fats, but also in some animal fats (horse, egg yolk); and (3) arachidonic acid, a tetraethenoid acid which is found in both the fat and the phosphatide fractions of many animal tissues, particularly in liver and in suprarenal phospholipides. The chemical characteristics of these representative straight-chain unsaturated fatty acids follow:

| <i>Common Name</i>    | <i>Empirical Formula</i> | <i>Number of Double Bonds</i> | <i>Chemical Name</i>       |
|-----------------------|--------------------------|-------------------------------|----------------------------|
| Oleic Acid.....       | $C_{18}H_{34}O_2$        | 1                             | 9-Octadecenoic             |
| Linoleic Acid.....    | $C_{18}H_{32}O_2$        | 2                             | 9,12-Octadecadienoic       |
| Linolenic Acid.....   | $C_{18}H_{30}O_2$        | 3                             | 9,12,15-Octadecatrienoic   |
| Arachidonic Acid..... | $C_{20}H_{32}O_2$        | 4                             | 5,8,11,14-Eicosatetraenoic |

From the empirical formulas it can be seen that oleic, linoleic, and linolenic acids may be considered derivatives of the saturated  $C_{18}$  acid, stearic acid, and arachidonic acid is an unsaturated form of the  $C_{20}$  acid, arachidic acid. Similar ethenoid derivatives are known of many of the other saturated fatty acids found in nature.

In addition to the straight-chain fatty acids so far described, a number of branched-chain and cyclic fatty acids, both saturated and unsaturated, have been isolated from natural sources. Tuberculostearic acid (10-methylstearic acid) has been obtained from the wax of the tubercle bacillus, as has phthioic acid, a methylated branched chain  $C_{26}$  acid which is possibly 3,13,19-trimethyltricosanoic acid, although this structure has been disputed. The latter appears to be associated with some of the clinical manifestations of tuberculosis. It is interesting to note that these and other fatty acids are found in tubercle wax as esters of the disaccharide trehalose (see Chapter 2). In chaulmoogra oil the unsaturated cyclic fatty acids chaulmoogric acid and hydnocarpic acid are found; these acids or their derivatives have been used in the treatment of leprosy.

**The Fats.** The fats are neutral esters of glycerol and fatty acids. An example is tristearin, synthesized in living tissues from one molecule of glycerol and three molecules of stearic acid:

Of the three molecules of fatty acid entering into the composition of a "true" or neutral fat, all may be the same, as in tristearin, in which case it is referred to as a simple triglyceride. However, more commonly two or three different fatty acids are involved, and such a fat is called a mixed glyceride, the composition being indicated by the name as oleodipalmitin, steardiolein, oleopalmitostearin, etc. Mixed glycerides occur much more commonly than do simple glycerides such as tristearin, tripalmitin, and triolein. The possibilities of stereoisomerism among the fats are many; they include isomerism due to the same fatty acids being arranged differently in the molecule, as well as optical isomerism when the middle carbon atom of the glycerol portion becomes asymmetric or when an optically active fatty acid is present. Such isomerism appears to be of much less physiological importance in the fats than in carbohydrates and proteins. Diglycerides (containing two fatty acids) and monoglycerides (containing one fatty acid) have been shown to be normal intermediates arising

in fat digestion. The 1,2-diglyceride and the 2-monoglyceride are believed to be the primary types.<sup>2</sup>

**Animal Fats.** Naturally occurring animal fats consist largely of mixed glycerides of oleic, palmitic, and stearic acid; furthermore they are usually mixtures of individual fats. Fats from various sources differ considerably in their fatty acid composition. Mutton fat contains more stearic acid and less oleic acid than pork fat. Human fats contain a high percentage of oleic acid. Butter fat consists largely of glycerides of palmitic and oleic acids, with small amounts of stearic acid and of the lower fatty acids such as butyric and caproic; significant variation in this connection may be noted from species to species (see Chapter 12).

**General Properties of Fats.** Pure neutral fats are odorless, tasteless, and generally colorless; the color of natural fats and oils is ordinarily due

FIG. 34. BEEF FAT.  
(Long)

FIG. 35. MUTTON FAT.  
(Long)

to pigments mixed with or dissolved in the fat. In the so-called *colored fats*, however, the chromogenic material is present in combination. Examples are chlorophyll, in which a colored acid is combined with a colorless alcohol (phytol); and colored waxes, in which colorless acids are esterified with colored alcohols (xanthophyll, capsanthin).<sup>3</sup> Fats are insoluble in all aqueous solvents, but are readily soluble in ether, benzene, chloroform, *boiling* alcohol, and other organic solvents, and this is the common basis for separating fats from other substances. The neutral fats are nonvolatile, and may be crystallized, some of them with great facility. The crystalline forms of some of the more common fats are reproduced in Figs. 34, 35, and 36. Each individual fat possesses a specific melting point, which depends upon the nature of the fatty acids in the molecule, and this property of melting at a definite temperature may be used as a means of differentiation if the fat is sufficiently pure. Tristearin, for example, melts at 71° C., tripalmitin at 66° C., and triolein at -5° C. In the glycerides containing saturated fatty acids, increase in molecular weight of the component fatty acids results in a higher melting point; the change from a saturated to an unsaturated fatty acid usually lowers the melting point.

<sup>2</sup> Mattson, Benedict, Martin, and Beck: *J. Nutrition*, **48**, 335 (1952).

<sup>3</sup> Zechmeister, in Schönfeld: *Chemie und Technologie der Fette und Fettprodukte*, Vol. I, Vienna, Springer, 1936, pp. 149-193.

Although most fats may exhibit sharp melting points under certain specified conditions, marked differences can be demonstrated between melting point and solidifying point. These discrepancies have been related to the fact that fats may occur in several polymorphic forms, depending upon the rate of cooling and the temperature at which they are maintained. The several forms are referred to as  $\alpha$ ,  $\beta$ ,  $\beta'$ , and  $\gamma$  types. They vary in stability, melting point, gross and microscopic appearance, x-ray diffraction pattern, crystal structure, density, and other properties. The  $\gamma$  form has the lowest melting point; the  $\alpha$ ,  $\beta'$  (when present) and  $\beta$  forms have progressively higher melting points. The polymorphic forms change to the  $\beta$  isomorph on standing; this is the most stable of the polymorphic

FIG. 36. PORK FAT.

forms. Ferguson and Lutton<sup>4</sup> reviewed the polymorphism of fats, and the melting points of the known modifications have been listed by Bailey.<sup>5</sup>

Mixed glycerides containing a high proportion of unsaturated fatty acids are usually liquid at room temperature, as indicated above, and are commonly called oils. These oils take up hydrogen at their double bonds, in the presence of catalysts such as finely divided nickel, and are thus converted into solid fats. This process is called *hardening* or *hydrogenation*. Many commercial fats are partially hydrogenated vegetable oils. There is no known nutritional objection to the use of properly hydrogenated vegetable oils in place of animal fats. For example, in experiments on rats and on man it was shown that hydrogenated vegetable oil was as satisfactorily digested and utilized as lard, and was less liable to cause gastric or intestinal symptoms of an objectionable nature.<sup>6</sup> Furthermore, under conditions in which oxidation may cause destruction of essential factors in the diet, the use of hydrogenated oil is claimed to be preferable to the use of unhydrogenated vegetable or animal fats.<sup>7</sup>

<sup>7</sup> Miller: *J. Nutrition*, **26**, 43 (1943).

When a fat is allowed to stand for a sufficient length of time in contact with air and moisture, particularly in the presence of light and heat, certain changes occur and it becomes rancid. Three types of rancidity have been described; namely, oxidative, ketonic, and hydrolytic. The first is the most important in the spoilage of fat. Rancid fats are unpalatable and appear to be slightly toxic for some individuals and destructive to other factors in the food such as carotene and vitamin A<sup>8</sup> and vitamin E.<sup>9</sup> The preservation of a mixed food is frequently a matter largely of the prevention of fat deterioration.

**Prevention of Rancidity by Antioxidants.** Compounds which retard the rate of development of rancidity in fats and oils are known as *antioxidants*. It is now generally agreed that oxidative rancidity proceeds by virtue of a chain reaction. The unsaturated fat first combines with oxygen to form a peroxide. This intermediate either spontaneously breaks down to an aldehyde or forms such a compound after interaction with water. The aldehyde in turn autoxidizes to a peracid, which oxidizes new, unsaturated linkages simultaneously with its transformation to an ordinary acid.

Antioxidants are able to disrupt this chain reaction. Thus after the oxidant (A) is changed to a peroxide (AO<sub>2</sub>), the antioxidant (B) behaves as follows:

By this series of changes the chain reaction is broken, the original unsaturated acid is restored, and the antioxidant is free to continue its protective action against oxidation at the double bonds. The antioxidants are active even in traces; one molecule of hydroquinone will protect 40,000 molecules of acrolein from oxidation.

Ordinarily, vegetable fats are much more resistant to spontaneous oxidation than are animal fats. This resistance is due to the presence in the former of natural antioxidants, referred to as *inhibitols*. Tocopherols (vitamins E) are the most effective antioxidants, the  $\delta$  isomer being the most and the  $\alpha$  isomer the least effective of the several naturally occurring tocopherols. Fats can be protected from spoilage by the use of a number of natural and artificial compounds, which include phenols and hydroquinones, NDGA (nordihydroguaiaretic acid), gum guaiac, propyl gallate, gallic acid, tannins and tannic acid, butylhydroxyanisole, and other related compounds. The effectiveness of the so-called inhibitols is markedly augmented by the presence of synergistic agents such as phosphoric acid, ascorbic acid, citric acid, and certain amino acids. *Prooxidants*, on the other hand, are substances which increase the susceptibility of fats to oxidation. These include certain carotenoids and chlorophyll, as well as copper and iron salts. Cyanide and the various acids just mentioned act as *antiprooxidants* in the sense that they "sequester" the oxidative metallic ions.

<sup>8</sup> Lease, Weber, and Steenbock: *J. Nutrition*, **16**, 571 (1938).

<sup>9</sup> Fitzhugh, Nelson, and Calvery: *Proc. Soc. Exptl. Biol. Med.*, **56**, 129 (1944).

**Emulsions.** When oil or liquid fat is shaken with water, it becomes finely divided and is dispersed in the water to form what is known as an emulsion. Emulsification with water alone is of course inefficient and transitory. In the presence of *emulsifying agents* dispersion of fat globules is more complete and hence more permanent. Among the important emulsifying agents are soaps, proteins, bile salts, mono- and diglycerides, and such technologically useful substances as the fatty acid esters of polymeric glycols or sugar alcohols like Myrj, Span, Tween, etc. Emulsifying agents act by lowering the surface tension of the aqueous phase and are presumably adsorbed on the surface of the tiny oil globules to form a film which minimizes the tendency of the globules to coalesce. A very fine powder which is wet by oil but not by water will likewise form a film around oil droplets and stabilize the emulsion. Oil-in-water emulsions are also stabilized by the use of gums which increase the viscosity of the aqueous or external phase. The formation of emulsions is of importance in pharmacy, in industrial practice, and in the processes of fat digestion in the intestinal tract.

**Hydrolysis of Fats.** Fats may be hydrolyzed by various agents, with the liberation of fatty acids and glycerol. Such agents are superheated steam, long-continued action of air and light, bacteria, and the enzyme lipase. When boiled with alkali the fats give glycerol and the metallic salt of the fatty acid.

This process is known as saponification, and the metallic salts of the higher fatty acids are known as soaps. The ordinary hard soaps of commerce are chiefly sodium soaps. Potassium forms soft soaps, of which green soap is an example. Calcium and magnesium form insoluble soaps. When ordinary soap is added to hard water a certain amount is used up in the precipitation of calcium and magnesium salts before the soap becomes effective. Lead salts also form insoluble soaps.

The detergent (cleansing) action of soaps is due largely to their ability to lower surface tension and thus facilitate emulsification of oily or greasy material, which can then be washed away. The commercial production of synthetic detergents has become of importance; these may be exemplified by one type which is a compound of sulfuric acid and cetyl alcohol,  $\text{C}_{16}\text{H}_{33}\text{OH}$ , the alcohol analogue of palmitic acid. Synthetic detergents act similarly to soaps by lowering surface tension; they are not inactivated by calcium and magnesium, however, and are therefore equally effective in hard and soft water, as the ordinary soaps are not.

**Methods Used in Study of Fats.** As the separation and identification of individual fats is a difficult matter, the properties commonly studied are of a general character. The *saponification value* of a fat is the number of milligrams of KOH required to neutralize the free or combined fatty acid in 1 g. of fat. It is determined by saponification and titration of excess alkali and is a measure of the mean molecular weight of the fatty acids present in the fat. The *Reichert-Meissl* number of a fat is a measure of the amount of volatile fatty acids and is determined by titration of the steam

distillate. The volatile fatty acids, which also include the soluble ones, are those containing ten or fewer carbon atoms. Butter is rich in these, but most butter substitutes are not. The determination of these acids is of use in detecting adulteration of butter.

The unsaturated fatty acids, of which oleic acid is an example, differ from the saturated acids in their power to take up iodine at the double bond.  $-\text{CH}=\text{CH}- + \text{I}_2 \rightarrow -\text{CHI}-\text{CHI}-$ . The *iodine value* is thus a measure of the amount of unsaturated fatty acid present in a fat. The more highly unsaturated fatty acids (di-, tri-, and tetraethenoid) are determined by their spectrophotometric absorption characteristics.

**Waxes.** The waxes are esters of fatty acids with monatomic alcohols. Examples are spermaceti, containing chiefly the palmitate of cetyl alcohol ( $\text{C}_{16}\text{H}_{33}\text{OH}$ ), and beeswax, consisting mainly of the palmitate of myricyl alcohol ( $\text{C}_{30}\text{H}_{61}\text{OH}$ ). They are saponified with greater difficulty than fats and are not attacked by lipase.

**Compound Lipides and Sterols.** See Chapter 11, Nervous Tissue and Chapter 18, Bile and Liver Function.

**Biological Importance of Fats.** Fats serve as a storage food in plant and animal organisms, and are of great importance for cellular processes, evidently along with other lipides. They are constituents of cell membranes, and are thus concerned with the phenomena of cell permeability and cell organization. The highly unsaturated fatty acids, linoleic and linolenic, appear to be necessary in the diet of certain animals to prevent a skin syndrome. (See Chapter 33 for a further discussion of fats and fat metabolism.)

## EXPERIMENTS ON FATS

**1. Fat Solvents.** Test the solubility of olive oil in water, dilute acid, and alkali; and in cold alcohol, hot alcohol, benzene, chloroform, ether, and carbon tetrachloride. (Cottonseed, soybean, or peanut oil may be used in place of olive oil in all the tests in this section.) Which are the best solvents for fats?

**2. Formation of a Translucent Spot on Paper.** Place a drop of olive oil upon a piece of ordinary writing paper. Note the semitransparent appearance of the paper at the point of contact with the fat.

**3. Reaction.** Try the reaction of fresh olive oil to litmus or other suitable indicator paper. (Moisten the paper with distilled water before making the test.) Repeat the test with rancid olive oil.<sup>10</sup> What is the reaction of a fresh fat and how does this reaction change upon allowing the fat to stand for some time?

**4. Formation of Acrolein from Olive Oil.** (a) Place about 0.5 inch powdered potassium bisulfate ( $\text{KHSO}_4$ ) in a clean, dry test tube. Drop no more than 3 or 4 drops of olive oil on the salt and heat, cautiously at first, and then more strongly. Note the irritating odor of acrolein. The glycerol of the fat is dehydrated and acrylic aldehyde or acrolein is produced. This is the reaction which takes place:

---

<sup>10</sup> To prepare rancid olive oil add 5 drops of oleic acid to 10 ml. of olive oil. Mix well.

(b) Repeat the above test using (1) 3 to 4 drops of oleic acid and (2) a little solid carbohydrate instead of olive oil. Heat vigorously and note the odor of  $\text{SO}_2$  in both tubes. Organic compounds reduce  $\text{KHSO}_4$  to  $\text{SO}_2$ , which is often mistaken for acrolein. Even fats, if heated too vigorously, yield  $\text{SO}_2$  as well as, or after, the acrolein.

**5. Emulsification.** (a) Shake up a drop of neutral<sup>11</sup> olive oil with a little water in a test tube. The fat becomes finely divided, forming an emulsion. This is not a permanent emulsion since the fat separates and rises to the top upon standing.

(b) To 5 ml. of water in a test tube add 2 or 3 drops of 0.5 per cent  $\text{Na}_2\text{CO}_3$ . Introduce into this faintly alkaline solution a drop of neutral olive oil and shake. The emulsion, while not permanent, is not so transitory as in the case of water free from sodium carbonate.

(c) Repeat (b), using rancid olive oil. What sort of emulsion results? In this case the alkali combines with the free fatty acid to form soap, and this soap, being an emulsifying agent, emulsifies the fat.

(d) Shake a drop of neutral olive oil with dilute albumin solution. What is the nature of this emulsion? Examine it under the microscope.

(e) Repeat (d), using bile salt solution instead of albumin solution. Compare the stability of the emulsion with that obtained in (a). What is one of the physiological functions of the bile?

**6. Fat Crystals.** Dissolve about 40 drops of melted lard in 10 ml. of ether in a test tube, stopper loosely with some filter paper, and allow the mixture to evaporate spontaneously until crystals begin to separate out. Transfer some of the material to a slide, examine the crystals under the microscope, and compare them with those reproduced in Figs. 34, 35, and 36.

**7. Saponification of Bayberry Tallow.**<sup>12</sup> Place about 10 g. of bayberry tallow in a 600-ml. beaker; add about 150 ml. of distilled water and 50 ml. of 10 per cent potassium hydroxide solution (not sodium hydroxide). Boil the mixture for 10 to 15 minutes, or until saponification is complete (no oily layer remaining on the surface). When saponification is complete,<sup>13</sup> remove 25 ml. of the hot soap solution, dilute it with about 100 ml. of distilled water, and reserve this solution for use in Exp. 8 and 9 below. To the remainder of the hot solution slowly add concentrated hydrochloric acid until the mixture is acid (about 10 ml. are required).<sup>14</sup> The free fatty acid formed will rise to the top as a clear oily layer. Now cool the solution, permitting the fatty acid to solidify and form a cake. In this instance the fatty acid is principally palmitic

<sup>11</sup> Neutral olive oil may be prepared by shaking ordinary olive oil with a 10 per cent solution of sodium carbonate. This mixture should then be extracted with ether and the ether removed by evaporation. The residue is neutral olive oil.

<sup>12</sup> Bayberry tallow is derived from the fatty covering of the berries of the wax myrtle. It is therefore frequently called *myrtle wax* or *bayberry wax*.

<sup>13</sup> Place 1 or 2 drops in a test tube full of hot distilled water. If saponification is complete, the soap formed will remain in solution and no oil will separate out.

<sup>14</sup> Under some conditions a purer product is obtained if the soap solution is cooled before precipitating the fatty acid.

acid. Remove the cake, break it into small pieces, wash it with water by decantation, and place in a beaker containing about 50 ml. of 95 per cent alcohol. Warm the mixture by placing the beaker in a vessel containing some hot water, until the palmitic acid is dissolved; then filter through a dry filter paper and allow the filtrate to cool slowly in order to obtain satisfactory crystals.

When the palmitic acid has completely crystallized, filter off the alcohol, dry the crystals between filter papers and by exposure to the air, and try the tests given in Exp. 11. Write the reactions which have taken place in this experiment.

8. *Salting-out of Soap.* To 100 ml. of soap solution, prepared as described above, add solid sodium chloride to the point of saturation, with continual

FIG. 37. PALMITIC ACID.

stirring. (If the soap has solidified due to cooling, dissolve it by warming before adding the salt.) The soap, which is in colloidal solution, is precipitated when its solution is saturated with sodium chloride. Why?

9. *Formation of Insoluble Soaps.* Introduce 5 ml. of soap solution into each of two test tubes. To the contents of one tube add a small amount of a solution of calcium chloride and to the contents of the other tube add a small amount of a solution of magnesium sulfate. Note the formation of insoluble soaps of calcium and magnesium.

10. *Surface Tension of Soap Solutions.* Determine the *drop number* of the soap solution as compared to pure water, as described on p. 23. What is the approximate surface tension of the soap solution relative to that of water? Is a drop of a soap solution equal in volume to a drop of an ordinary aqueous solution?

11. *Palmitic Acid.* (a) MICROSCOPIC: Examine the crystals under the microscope and compare them with those shown in Fig. 37.

(b) SOLUBILITY. Test the solubility of palmitic acid in the same solvents as used on fats (see p. 106).

(c) **MELTING POINT.** Determine the melting point of palmitic acid by any standard method. A value lower than the theoretical will be obtained because of the presence of impurities.

(d) **FORMATION OF TRANSLUCENT SPOT ON PAPER.** Melt a little of the fatty acid and allow a drop to fall upon a piece of ordinary writing paper. How does this compare with the action of a fat under similar circumstances?

(e) **ACROLEIN TEST.** Apply the test as given under 4, p. 106. Explain the result.

(f) **IODINE ABSORPTION TEST.** For directions see Exp. 14.

**12. Saponification of Lard.** To 25 g. of lard in a flask add 75 ml. of alcoholic-potash solution<sup>15</sup> and warm on a water bath until saponification is complete. (This point is indicated by the complete solubility of a drop of the solution when allowed to fall into a little distilled water.) Now transfer the solution from the flask to an evaporating dish containing about 100 ml. of water and heat on a water bath until all the alcohol has been driven off. Acidify the solution with hydrochloric acid and cool. Remove the fatty acid which rises to the surface,<sup>16</sup> neutralize the solution with sodium carbonate, and evaporate to dryness. Extract the residue with alcohol, remove the alcohol by evaporation on a water bath, and on the residue of glycerol thus obtained make the tests as given below.

**13. Glycerol.** (a) **TASTE.** What is the taste of glycerol?

(b) **SOLUBILITY.** Try the solubility of glycerol in water, alcohol, and ether.

(c) **ACROLEIN TEST.** Repeat the test as given under 4, p. 106, using 2 drops of glycerol.

(d) **BORAX FUSION TEST.** Fuse a paste of glycerol and powdered borax on a platinum wire and note the characteristic green flame. This color is due to the glycerol ester of boric acid.

(e) **BENEDICT'S TEST.** Add a few drops of glycerol to 5 ml. of Benedict's reagent and boil for 2 to 3 minutes. How does the result compare with the results on the sugars?

(f) **SOLUTION OF  $\text{Cu}(\text{OH})_2$ .** Form a little cupric hydroxide by mixing copper sulfate and sodium hydroxide. Add a little glycerol to this suspended precipitate and note what occurs. Explain.

**14. Iodine Absorption Test.** Dissolve 5 to 10 drops of an unsaturated organic acid, e.g., oleic acid, in about 5 ml. of chloroform. Add some Hübl's iodine solution,<sup>17</sup> a drop or two at a time, and shake between additions. The solution will be decolorized if unsaturated acids are present. This is due to the absorption of the iodine. The test should be controlled by shaking chloroform and iodine solution to which no acid has been added.

**15. Determination of Saponification Number.** Measure 5 ml. of oil into a 250-ml. Erlenmeyer flask with a clean dry pipet. Calculate the weight of the oil from the specific gravity. (The specific gravity of olive oil is 0.916.) (Direct weighing of the oil is more accurate.) Add 50 ml. of alcoholic 0.5 N KOH (made up in 90 per cent alcohol) from a pipet. To another flask not containing oil add a similar 50-ml. portion of the KOH. Fit each flask with a reflux air condenser and boil by immersion in a large beaker of boiling water for half an hour with frequent agitation. Add to each flask 1 ml. of 1 per cent alcoholic

<sup>15</sup> A 20 per cent solution in 40 per cent alcohol may be used.

<sup>16</sup> After drying the acid make an iodine absorption test as described in Exp. 14.

<sup>17</sup> See Appendix.

solution of phenolphthalein and titrate with 0.5 N HCl. Subtract the titration value of the control from that of the unknown. One ml. of the HCl is equivalent to 0.02805 g. of KOH. Calculate the number of mg. of KOH required to saponify 1 g. of the oil.

**16. Determination of Iodine Absorption Number.** With a clean dry pipet measure 0.3 ml. of oil into a dry 100-ml. Erlenmeyer flask. Calculate the weight of the oil from the specific gravity. (For accurate work the oil must be weighed.) Add 10 ml. of carbon tetrachloride and after solution of the oil add exactly 25 ml. of Wijs' iodine solution.<sup>18</sup> Mix well, stopper, and put in a dark place for 1 to 2 hours. Transfer quantitatively to a 500-ml. flask, washing out the small flask with 10 ml. of 10 per cent KI solution and with water to make a volume of about 250 ml. Titrate with thiosulfate to a light brown color, add starch paste and titrate to disappearance of the blue color. After the blue color has disappeared from the aqueous phase, the carbon tetrachloride layer in the bottom of the flask usually contains untitrated iodine as evidenced by a pink or violet color. This iodine may be brought into the aqueous layer by continuous shaking. The end point of the titration is reached when both the aqueous and nonaqueous phases are completely colorless. Calculate the number of centigrams of iodine absorbed by 1 g. of fat. This is the iodine absorption number, or the iodine value, of the oil.

# Proteins: Their Composition and Hydrolysis; Amino Acids

### PROTEINS

**Definition.** Proteins have been defined as extremely complex nitrogen-containing organic compounds which are found in all animal and vegetable cells, where they constitute a major part of the living protoplasm of those cells. The Dutch physiological chemist G. J. Mulder, who at the suggestion of the famous chemist, Berzelius, derived the word protein from the Greek *πρωτος*, "first," said in 1840: "In both plants and animals a substance is contained which is produced within the former, and imparted through the food to the latter. It is one of the most complicated substances, is very changeable in composition. . . . It is unquestionably the most important of all known substances in the organic kingdom. Without it no life appears possible on our planet. Through its means the chief phenomena of life are produced." Proteins, carbohydrates, and fats form the three great classes of foodstuffs, but the function of protein in the diet is not primarily to supply energy, as is true of the other two, but to furnish certain essential components of the living tissue of the organism itself. Although plants, including many bacteria, are capable of synthesizing proteins from simple organic and inorganic nitrogenous compounds, this ability has been lost to such an extent by the higher animals that they must depend upon preformed proteins or rather certain of their specific degradation products, the  $\alpha$ -amino acids, for the continuance of life.

The capacity of the living organism for storing proteins is limited and relatively small when compared to its capacity for storing carbohydrates and fats. Proteins are, however, stored under special conditions as in eggs and seeds for use by the developing or immature organism until it can obtain food from its environment. Although the carbohydrates and lipides are both essential constituents of the colloidal complex which we call protoplasm, the proteins are of paramount importance not only because of their peculiar chemical and physicochemical properties but also because they appear to confer upon various types of cells their biological specificity. In the main, identical lipides and carbohydrates may be found in cells of both plants and animals of widely different species; the proteins, however, are usually highly characteristic of the species of plant or animal, and, more often than not, of the specific organ in which they are found.

**Composition.** The proteins differ from carbohydrates and fats not only in their function in the organism, but also in elementary composition.

In addition to carbon, hydrogen, and oxygen, the proteins invariably contain nitrogen and generally also sulfur. The percentage composition of the large number of proteins from different sources which have been studied falls between the following rather narrow limits: C = 50 to 55 per cent, H = 6.0 to 7.3 per cent, O = 19 to 24 per cent, N = 13 to 19 per cent, S = 0 to 4 per cent. Proteins have also been described which contain phosphorus, iron, copper, iodine, manganese, zinc, and other elements. None of these latter elements, with the exception of iodine, has thus far been found as a constituent of the  $\alpha$ -amino acids, the fundamental units from which proteins are built up by the organism, and until we have more exact information concerning the composition and structure of the protein molecule, we may assume that these elements are combined with protein in some unknown way, or, as has been shown in the case of iron, that they are constituents of nonprotein substances which are combined with protein in a way which confers new and characteristic properties upon the complex formed.

**General Properties.** The almost infinite number of proteins which are present in nature give certain reactions which serve to identify them as a distinct class of biological substances. Almost all soluble proteins form colloidal solutions. This indicates either that the molecules of protein are so large that even when dispersed in molecular solution they have the properties of size and surface which characterize colloidal particles, or else that there is some force connected with protein molecules which predisposes them to form aggregates of colloidal size. There are good reasons for believing that the colloidal properties of protein solutions are due in some cases to the first and in other cases to the second of these possibilities. The colloidal solutions formed by proteins are of the emulsoid type, thus requiring large concentrations of electrolytes for precipitation. The proteins give certain color reactions which, however, are not specific for the protein molecule as such but for various chemical groups which it is thus shown to contain. Although proteins generally precipitate from their solutions in an amorphous condition, many of them have been isolated from both animal and vegetable sources in the form of characteristic crystals. The proteins are precipitated from their solutions by salts of heavy metals, such as silver nitrate, lead acetate, etc.; by acids such as tannic acid, phosphotungstic acid, metaphosphoric acid, etc.; and by many dyes and detergents. These precipitation reactions are probably due, in part at least, to the formation of insoluble compounds of the protein and the precipitating agent and in part to the colloidal character of protein solutions. The proteins exhibit amphoteric properties, combining with both acids and bases to form ionizable salts. Finally, upon complete hydrolysis the proteins yield crystalline substances of definite composition belonging to the class of compounds known as  $\alpha$ -amino acids.

**Investigation of Protein Composition.** The constancy in elementary composition of proteins from widely differing sources and the great individual differences in chemical and physical properties preclude elementary analysis as a method of characterizing individual proteins. There are, however, four main lines of attack used in the investigation of the protein molecule: (1) Complete hydrolysis of the protein into its con-

stituent units, the  $\alpha$ -amino acids; (2) partial hydrolysis to yield relatively small degradation products (di- and tripeptides, etc.) which are capable of separation and complete characterization; (3) stepwise degradation, that is, removing one amino acid after another from one end of the polypeptide chain; and (4) the study of the physicochemical, colloid-chemical, and biological reactions of the completely intact molecule as well as of the slightly changed (denatured) molecule. Until comparatively recently the method of complete hydrolysis was the one most commonly employed. This procedure is of great importance since it yields the individual units from which the protein is formed. However, just as elementary analysis of the less complex organic molecules tells us the percentage composition of the substance under examination without indicating the atomic arrangement within the molecule, so complete hydrolysis of a protein reveals the quantities of the various constituent amino acids without giving much indication as to their special arrangement within the giant molecule. In order to reveal the great individual differences among proteins and to gain an insight into their specific biological functions, such as the hormonal action of insulin, the enzymatic effects of pepsin, the role of myosin in muscle contraction, the pathogenicity of tobacco mosaic virus, etc., all four modes of study must be used. The work of the chemist, biologist, physicist, and analyst must be known and appreciated by each member of the team before the problem of the complete structure of even one protein is to be solved.

**Hydrolysis.** Hydrolysis of proteins may be effected: (1) By boiling with mineral acids or strong alkalies, at atmospheric or increased pressures, (2) by treatment with certain long-chain sulfonic acids (cetyl-sulfonic acid, diphenylbenzenesulfonic acid, etc.), and (3) by digestion with proteolytic enzymes. Commonly, hydrolysis of a protein is carried out by boiling it with five to ten times its weight of 6 N hydrochloric acid or 8 N sulfuric acid for 6 to 24 hours. Under special circumstances other reagents, such as hydriodic acid, oxalic acid, 5 N sodium hydroxide, hot saturated barium hydroxide, or a mixture of formic and hydrochloric acids, can be used. Acid hydrolysis, especially if the protein contains carbohydrate, usually results in the complete destruction of the amino acid tryptophan, and may result in the partial decomposition of certain other amino acids. The prolonged heating necessary to effect complete hydrolysis by strong alkalies does not affect tryptophan, but results in the partial or complete destruction of cysteine, cystine, and arginine, and in the racemization and consequent loss of optical activity of all the amino acids. Enzymatic hydrolysis has none of these disadvantages of acid or alkaline hydrolysis but it is very time-consuming and is seldom complete. Hydrolysis of proteins with the above-mentioned sulfonic acids requires further investigation.

Hydrolysis of the protein molecule by any of the methods above leads to the formation of a series of ill-defined fragments of decreasing complexity known as proteoses, peptones, and polypeptides, the final products being amino acids. Certain amino acids are split off early in the hydrolytic process. This liberation of amino acids continues until the larger intermediate fragments have all been reduced to these simpler com-

pounds. Physically the hydrolysis of proteins consists in a breaking down of the large, colloidal, nondiffusible complexes into a series of fragments in which the colloidal character becomes less and less pronounced, until finally only the simple, crystalloidal, and diffusible amino acids remain. Since the amino acids represent, therefore, the "building stones" of the protein molecule, we may well begin the study of that molecule by a consideration of the structure and reactions of these fundamental units.

## AMINO ACIDS

The amino acids thus far isolated from protein hydrolyzates are  $\alpha$ -amino acids—that is, they have an amino ( $\text{NH}_2$ ) group attached to the same carbon atom that holds the carboxyl ( $\text{COOH}$ ) group. Their general formula<sup>1</sup> is therefore

Individual amino acids differ in the character of the radical R attached to the  $\alpha$  carbon atom.

## CLASSIFICATION

The amino acids may be conveniently classified according to the number of their amino and carboxyl groups, as follows: (1) Neutral amino acids, containing one amino and one carboxyl group, (2) acidic amino acids, containing an excess of carboxyl groups, and (3) basic amino acids, containing an excess of basic nitrogen. The amino acids in each group may be further subdivided according to whether the radical R in the general formula represents an aliphatic, aromatic, or heterocyclic nucleus.

### NEUTRAL AMINO ACIDS

These acids are often referred to as monoamino-monocarboxylic acids because they contain one amino and one carboxyl group. Solutions of these acids react essentially neutral. These acids form the largest group in the protein molecule and most of them may be separated in one fraction from the products of protein hydrolysis. Because of their great chemical and physical similarities, the isolation of the individual acids in this fraction presents experimental difficulties.

#### A. ALIPHATIC AMINO ACIDS

##### 1. Glycine, $\text{C}_2\text{H}_5\text{O}_2\text{N}$ (aminoacetic acid)

<sup>1</sup> The only exceptions to this general formula are found with the two amino acids proline and hydroxyproline (*q.v.*), in which the  $\alpha$ -nitrogen is part of a cyclic structure.

2. **Alanine**,  $C_3H_7O_2N$  ( $\alpha$ -aminopropionic acid)

3. **Serine**,  $C_3H_7O_3N$  ( $\beta$ -hydroxy- $\alpha$ -aminopropionic acid or  $\beta$ -hydroxy-alanine)

4. **Threonine**,  $C_4H_9O_3N$  ( $\alpha$ -amino- $\beta$ -hydroxy-*n*-butyric acid)

5. **Valine**,  $C_5H_{11}O_2N$  ( $\alpha$ -aminoisovaleric acid or  $\beta,\beta$ -dimethylalanine)

6. **Leucine**,  $C_6H_{13}O_2N$  ( $\alpha$ -aminoisocaproic acid or  $\beta$ -isopropylalanine)

7. **Isoleucine**,  $C_6H_{13}O_2N$  ( $\beta$ -methyl- $\alpha$ -aminovaleric acid or  $\beta$ -methyl- $\beta$ -ethylalanine)

B. AROMATIC AMINO ACIDS

8. **Phenylalanine**,  $C_9H_{11}O_2N$  ( $\beta$ -phenyl- $\alpha$ -aminopropionic acid or  $\beta$ -phenylalanine)

**9. Tyrosine**,  $C_9H_{11}O_3N$  ( $\beta$ -parahydroxyphenyl- $\alpha$ -aminopropionic acid or  $\beta$ -parahydroxyphenylalanine)

#### C. SULFUR-CONTAINING AMINO ACIDS

**10. Cysteine**,  $C_3H_7O_2NS$  ( $\beta$ -thiol- $\alpha$ -aminopropionic acid)

**11. Cystine**,<sup>2</sup>  $C_6H_{12}O_4N_2S_2$  (di-( $\beta$ -thiol- $\alpha$ -aminopropionic acid))

**12. Methionine**,  $C_5H_{11}O_2NS$  ( $\gamma$ -methylthiol- $\alpha$ -amino-*n*-butyric acid)

#### D. HETEROCYCLIC AMINO ACIDS

**13. Tryptophan**,  $C_{11}H_{12}O_2N_2$  ( $\beta$ -3-indole- $\alpha$ -aminopropionic acid or  $\beta$ -indolealanine)

<sup>2</sup> Cystine is included here among the monoamino-monocarboxylic acids because it contains equal numbers of amino and carboxyl groups.

**14. Proline,  $C_5H_9O_2N$**  (pyrrolidine-2-carboxylic acid)**15. Hydroxyproline,  $C_5H_9O_3N$**  (oxyproline or 4-hydroxypyrrolidine-2-carboxylic acid)

## ACIDIC AMINO ACIDS

These acids, often referred to as monoamino-dicarboxylic acids, contain more carboxyl than amino groups and are therefore acid in reaction. The acidic nature of glutamic acid and aspartic acid allows their ready separation from the other components of protein hydrolyzates.

**16. Aspartic acid,  $C_4H_7O_4N$**  ( $\alpha$ -aminosuccinic acid)**17. Glutamic acid,  $C_5H_9O_4N$**  ( $\alpha$ -aminoglutaric acid)

## BASIC AMINO ACIDS

These acids are predominantly basic in reaction and are precipitated from protein hydrolyzates by the addition of phosphotungstic acid<sup>3</sup> or they may be selectively adsorbed on weak cation exchange resins.

<sup>3</sup> Proline and cystine are also precipitated to a certain extent by phosphotungstic acid.

**18. Histidine,**  $C_6H_9O_2N_3$  ( $\beta$ -imidazole- $\alpha$ -aminopropionic acid or  $\beta$ -imidazolealanine)

**19. Arginine,**  $C_6H_{14}O_2N_4$  ( $\delta$ -guanidino- $\alpha$ -aminovaleric acid)

**20. Lysine,**  $C_6H_{14}O_2N_2$  ( $\alpha$ - $\epsilon$ -diaminocaproic acid)

**21. Hydroxylysine,**  $C_6H_{14}O_3N_2$  ( $\alpha$ - $\epsilon$ -diamino- $\delta$ -hydroxycaproic acid).

**22. Citrulline,**  $C_6H_{13}O_3N_3$  ( $\delta$ -carbamino- $\alpha$ -aminovaleric acid)

**Other Hydrolysis Products of Proteins.** Most proteins contain practically all of the amino acids listed above. Occasionally we find that certain amino acids are either entirely absent in a particular protein, or else present in amounts too small to be detected by the available methods of analysis. Thus the protein zein, from maize, contains no lysine or glycine, gelatin yields no tryptophan, and insulin contains no methionine. In other cases we may find that certain specialized proteins contain amino acids not found in any other proteins. The most noteworthy example of this is a globulin obtained from the thyroid gland, thyroglobulin, which normally contains the iodinated tyrosine derivatives, monoiodotyrosine;

3, 5-diiodotyrosine, or iodogorgoic acid; and  $\beta$ -4'-hydroxyphenyl-3',5',3,5-tetraiodotyrosine, or thyroxine. Interestingly enough the bromine analogues of iodotyrosines—namely monobromotyrosine and dibromotyrosine—have been found in a number of Mediterranean corals and Gorgonia.

Other Porifera and coelenterates yield monoiodotyrosine, diiodotyrosine, and even traces of thyroxine.

Occasionally substances known as diketopiperazines, which are anhydrides formed by the condensation of two molecules of amino acid, have been found in protein hydrolyzates. It is probable that these are formed during the treatment of the hydrolyzate.

In addition to the above-mentioned amino acids, there are other less well-recognized amino acids in many peptide molecules. Thus  $\alpha$ - $\epsilon$ -diaminopimelic acid has been found in the insoluble proteins of the microorganism *Corynebacterium diphtheriae*; and iodinated histidine has been reported to be present in pancreatic digests of thyroglobulin.

Acid hydrolysis of proteins also liberates variable quantities of ammonia which come primarily from the hydrolysis of the acid amide groups of asparagine and glutamine, for it is now known that a portion of these dicarboxylic amino acids exists in the peptide chain with the "omega" carboxyl group aminated. A smaller portion of the ammonia presumably comes from the hydrolytic decomposition of certain amino acids such as cysteine, serine, threonine, etc. If alkaline hydrolysis is employed, ammonia is formed from glutamine, asparagine, cystine, cysteine, serine, threonine, and arginine. The last-named substance breaks down to yield ornithine and two molecules of ammonia.

Hydrolysis of proteins also yields small quantities of carbon dioxide, hydrogen sulfide, and free sulfur. These products arise from the destructive decomposition of the more labile amino acids, especially cysteine. Many proteins (serum albumin, egg albumin, thrombin) yield varying amounts of carbohydrate. These carbohydrates appear to be polysaccharides composed of glucosamine and hexose (mannose, galactose). It is not known whether the carbohydrates are an integral part of the protein molecule or whether the protein is composed of a carbohydrate-free portion admixed with a small quantity of a carbohydrate-rich protein (glycoprotein) such as seromucoid, seroglycoid, ovomucoid, etc.

**Determination of Amino Acids.** The quantitative determination of each of the component amino acids produced during hydrolysis of a protein is a problem of greatest importance since any theory of protein structure must rest ultimately on an exact knowledge of all the units contained in the molecule. This problem is still far from solved since it presents many serious difficulties, not least of which is the preliminary hydrolysis of the protein molecule into its component amino acids without causing decomposition during the hydrolysis.

\* Calculated in g. of amino acid per 16.0 g. of nitrogen.

METHODS. *A. Fractional Distillation of Ethyl Esters.* Fischer in 1901 showed that most neutral amino acids formed esters when their solutions in absolute ethyl alcohol were treated with dry hydrogen chloride. The amino acid esters were separated by fractional distillation *in vacuo*. Using this method, Fischer was able to isolate many of the amino acids in pure crystalline form. The method, however, is very tedious, requires large quantities of protein, and does not yield quantitative results.

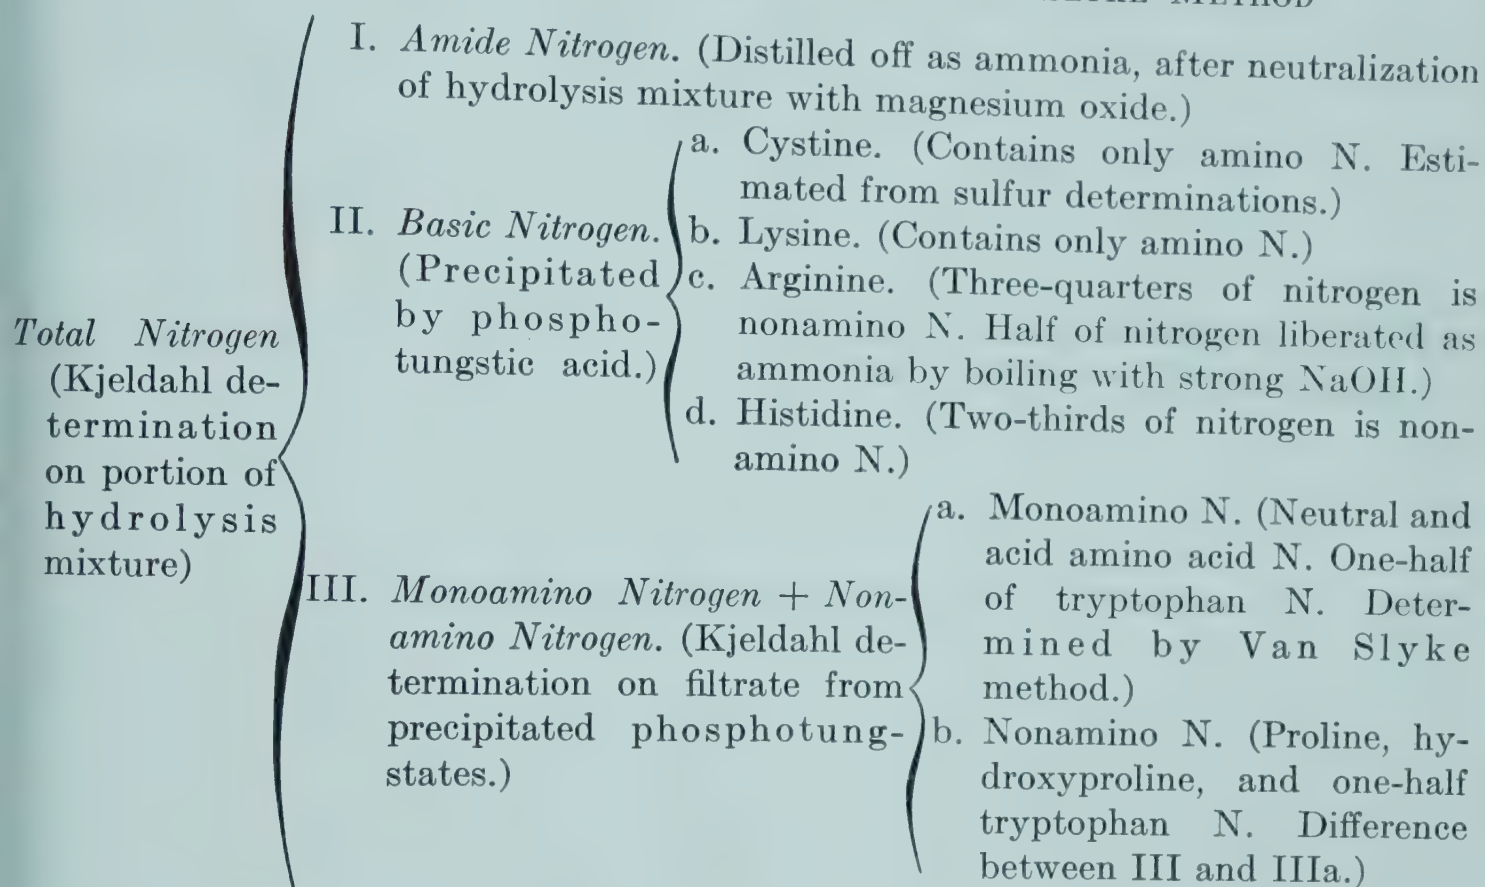

*B. Van Slyke's Nitrogen-Distribution Method.* When an aliphatic primary amine is treated with nitrous acid, its amino nitrogen is quantitatively converted into free nitrogen.

By the use of this reaction, supplemented by other procedures as indicated in the accompanying diagram, Van Slyke developed a method for the determination of the distribution of amino and nonamino nitrogen in the protein together with fairly accurate determinations of cystine, arginine, lysine, and histidine.

#### DISTRIBUTION OF PROTEIN NITROGEN BY VAN SLYKE METHOD

*C. Determination of Individual Amino Acids.* Differences in the chemical nature of the various amino acids have been utilized to permit the estimation by chemical means of the quantities of individual amino acids present in a protein hydrolyzate. The principal methods in use at the present time are outlined below:

1. Glycine in a protein hydrolyzate is oxidized with ninhydrin (triketohydrindene hydrate) to yield formaldehyde.
2. Alanine is oxidized with ninhydrin to yield acetaldehyde.
3. Serine is oxidized with periodic acid to yield formaldehyde which is readily determined.
4. Threonine is oxidized with periodic acid to yield acetaldehyde.
5. Phenylalanine is first nitrated to yield 3,4-dinitrophenylalanine; this is reduced to the nitroso compound, which has a purple color in alkaline solution.
6. Tyrosine, like other 3,5 unsubstituted phenols, gives an intense red color when treated with mercury salts and nitrous acid (Millon-Nasse reaction).
7. Tryptophan gives various red and purple compounds when con-

\* Calculated in g. of amino acid per 16.0 g. of nitrogen.

condensed with aromatic or aliphatic aldehydes in the presence of concentrated hydrochloric or sulfuric acid (Hopkins-Cole, Voisenet-Rhode reactions).

8. Cystine is reduced to cysteine. The latter is capable of reducing phospho-18-tungstic acid to yield the deep-blue lower oxides of tungsten.

9. Methionine is treated with sodium nitroprusside to give a colored complex.

10. Aspartic acid is first precipitated as the calcium salt and then is isolated as copper aspartate.

11. Glutamic acid is oxidized with chloramine-T to  $\beta$ -cyanopropionic acid. The latter is hydrolyzed to succinic acid which is then determined.

12. Histidine is precipitated as the silver salt at pH 7.4 and then isolated as histidine nitranilate. Nitranilic acid is 2,5-dihydroxy-3,6-dinitro-*p*-benzoquinone.

13. Arginine is first precipitated by silver nitrate and baryta at strongly alkaline reaction and then isolated as pure arginine 2,4-dinitro-1-naphthol-7-sulfonate (arginine monoflavianate).

14. Lysine can be determined in the intact protein by virtue of the fact that almost all of the free amino groups in a protein are the  $\epsilon$ -amino groups of lysine. Lysine is isolated from a protein hydrolyzate previously freed of histidine and arginine, by precipitation with phospho-24-tungstic acid and subsequent isolation as lysine picrate.

15. Hydroxylysine is precipitated with phosphotungstic acid. On treatment with periodic acid in alkaline solution, one molecule of hydroxylysine yields one molecule of formaldehyde and one of ammonia.

*D. The Isotope Dilution Method of Ussing and of Schoenheimer and Rittenberg.* A compound which has an abnormal isotope content is inseparable from its normal analogue by the usual laboratory procedures. Thus if an amino acid containing a known excess of an isotope is added to a protein hydrolyzate, the quantity of the amino acid present in the hydrolyzate can be calculated by a determination of the isotope content of the isolated amino acid. The yield of amino acid actually isolated is of no importance in this method.

*Isotopic-Carrier Method.* A mixture of amino acids is treated with a reagent containing stable or radioactive isotopes to form quantitatively a stable derivative of the desired constituent. Then an overwhelming excess,  $W$ , of the unlabeled derivative (the carrier) is added. The carrier is isolated and purified to constant isotope concentration  $C_c$ .

If  $C_r$  is the isotopic concentration of the pure isotopic derivative prepared with the same reagent, the quantity of derivative present is  $W \times C_c/C_r$ . Thus, one isotopic reagent suffices for the analysis of many compounds.

*E. Microbiological Procedures.* Various microorganisms such as *Lactobacillus arabinosus*, etc., require certain amino acids for normal growth (see p. 1062). Preparation of synthetic media lacking in only one of these amino acids permits the determination of the specific amino acid in the unknown solution. Growth of the microorganism on the synthetic medium supplemented by the solution undergoing analysis is compared with that obtained in the presence of known amounts of added amino acid. In

other cases, mutants of the mold *Neurospora crassa* have been developed which require only one amino acid for growth. A number of enzymes have been separated from plant and animal sources, each of which decomposes only a single amino acid in a mixture. Thus arginine may be determined by the action of arginase, which liberates ammonia; tyrosine, histidine, lysine, and glutamic acid are each decarboxylated by specific enzymes. Quantitative determination of the carbon dioxide thus liberated is a measure of the amino acid present.

*F. Chromatographic and Ion-Exchange Methods.* The powerful analytical tools of paper chromatography and ion-exchange chromatography have not only been applied to the qualitative and quantitative determination of all the amino acids which commonly occur in protein hydrolyzates but have enabled investigators to find hitherto unsuspected amino acids, e.g., moniodotyrosine,  $\beta$ -hydroxyphenyl-triiodotyrosine, diaminopimelic acid, etc. Plate I shows the separation of the amino acids in a protein (keratin from wool fiber) hydrolyzate on a two-dimensional paper chromatogram after staining with ninhydrin. This type of chromatogram is excellent for the qualitative identification of amino acids and it may be employed, under proper conditions, for their quantitative estimation. The quantitative or, more usually, semiquantitative estimation is based on the observation that the maximum color density of each spot is proportional to the concentration of material at that spot.

The amino acids may also be separated one from another by first adsorbing the mixture on a column of a polystyrene cation-exchange resin. The individual amino acids are then eluted from the resin with buffers of progressively increasing pH. Many small fractions of the eluate are collected separately and each fraction is analyzed for its amino acid content by heating with ninhydrin. From the data thus obtained, the quantity and identity of each amino acid in the mixture may be computed.

*G. Electrolytic Separations.* The  $\alpha$ -amino acids may be divided into three groups—neutral, acidic, basic—by virtue of their charge in solutions of definite hydrogen-ion concentrations. Electrolytic separations are employed preliminary to paper chromatography.

**General Properties of Amino Acids.** The amino acids derived from proteins are all  $\alpha$ -amino acids. The  $\alpha$  carbon atom in all the acids, with the exception of glycine, is asymmetric, so that these acids are all optically active. They are white crystalline substances, the crystal form being characteristic for each acid. They are all soluble in water, except cystine and tyrosine, the latter being more soluble in hot than in cold water. With the exception of proline, they are all insoluble in alcohol, and all are insoluble in ether. They are, as a rule, all soluble in solutions of strong acids and bases. They are not precipitated by ammonium sulfate or sodium chloride, but with the exception of proline are precipitated by alcohol. They form crystalline salts with metallic bases and with mineral acids. Many of the amino acids (such as glycine, alanine, serine, and proline) have a sweet taste; some, like tryptophan and leucine, are tasteless; others, like arginine, are bitter. The amino acids are all amphoteric, ionizing both as acids and as bases by virtue of their carboxyl and amino groups, thus forming salts with alkalies and with acids.

**Spatial Configuration and Optical Activity of Amino Acids.** The amino acids have the following general structure:

In this structure the  $\alpha$  carbon atom is asymmetric—i.e., there are four different substituent groups. Thus all the amino acids except glycine (where  $\text{R} = \text{H}$ ) are optically active, and are capable of existing in two different spatial forms, which are mirror images of one another, with equal and opposite optical rotatory power, and which differ solely in the arrangement of the substituent groups in space around the  $\alpha$  carbon atom. These two different spatial arrangements are known respectively as the D and L configurations.

The configuration of a particular amino acid is based on its spatial relationship to an arbitrary reference compound, just as the configuration of D-glucose is based on that of dextrorotatory D-glyceraldehyde (see Chapter 2). This relationship, for the amino acids, is illustrated as follows:

Thus the naturally occurring amino acid alanine, which is dextrorotatory, may by suitable means be related structurally to either dextrorotatory lactic acid or levorotatory glyceraldehyde. Both of these have the same configuration, which in this case is known as the L configuration when referring to amino acids. As with the sugars, there is no necessary agreement between configuration and the direction of optical rotation; to indicate the latter, the signs (+) for dextrorotatory and (−) for levorotatory are used. Naturally occurring alanine is therefore L(+)-alanine; its mirror image is D(−)-alanine.

The spatial configuration of an amino acid appears to have important physiological significance. For instance, certain (but not all) of the amino acids cannot be utilized by the animal body if the configuration is opposite to that found naturally. It is an interesting fact that the bulk of the amino acids found in nature, either free or as part of proteins, have the L configuration. Certain D amino acids have however been isolated from natural sources: thus D glutamic acid is a major constituent of the capsule of *Bacillus anthracis* and related microorganisms; the naturally occurring antibiotic polypeptide, gramicidin, contains a high proportion of D amino acids; and D valine is a decomposition product of the penicillins. The significance of these stereochemical findings remains to be elucidated.

**Chemical Reactions of Amino Acids.** The amino acids give three general types of chemical reactions: (1) Reactions due to the presence in the molecule of the carboxyl (COOH) group, (2) reactions due to the amino (NH<sub>2</sub>) group, and (3) reactions due to the radical R. Of these three types of reactions, those due to the carboxyl and amino groups are perfectly general reactions and are given by all the amino acids.

The reactions given by the radical R are usually specific reactions, given only by those acids which contain certain particular groups. Thus cystine gives a reaction for sulfur, tryptophan gives certain color reactions because its molecule contains the indole group, tyrosine gives other color reactions because of its phenolic group, etc. Some of these color reactions that are specific for individual amino acids are used as general color reactions for proteins since most proteins contain one or more of these acids in their molecules. The most important of these reactions are therefore described in the next chapter, under the general reactions of proteins.

The reactions given by all amino acids by virtue of their carboxyl and amino groups are of great importance. Some of these reactions, such as the formation of a great variety of crystalline derivatives with organic and inorganic compounds, are useful in the isolation, purification, and quantitative determination of individual amino acids. Among such derivatives we may mention the ethyl esters, picrates, flavianates, picrolonates, copper, barium, cadmium, calcium, nickel, and zinc salts, and double salts with compounds such as phosphotungstic acid, chloroplatinic acid, gold chloride, silver nitrate, mercuric acetate, and mercuric chloride. Many of these reactions are given by the intact protein, since the latter always contains a certain number of free amino and carboxyl groups. The more important of these reactions of amino acids which give us an insight into the complex chemical and physicochemical behavior of the protein molecule are discussed below.

**REACTIONS OF AMINO ACIDS WITH ACIDS AND BASES.** Since the amino acids contain both carboxyl and amino groups, they behave like typical amphoteric compounds, ionizing both as acids and as bases:

The addition of acid favors the ionization to the left and leads to the formation of salts of the amino acid similar to those formed by ammonia and other substituted ammonia derivatives. With hydrochloric acid, for example, a hydrochloride is formed which ionizes into a positive amino acid ion and a negative chlorine ion:

With alkalis, such as sodium hydroxide, the ionization proceeds to the right and leads to the formation of a sodium salt of the amino acid, which is ionized. This gives a positive sodium ion and a negative amino acid ion:

In acid solutions, therefore, the amino acid carries a positive charge and in an electrical field migrates to the cathode, but in alkaline solutions it carries a negative charge and migrates to the anode. For every amino acid there is a definite hydrogen-ion concentration, specific for that acid, at which the degrees of acid and basic ionization are equal. At this particular pH, known as the isoelectric point, the amino acid is electrically neutral and will not migrate in an electrical field.

In past years there has been a great accumulation of experimental evidence indicating that this electrically neutral form of the amino acid consists of a mixture of undissociated molecules and a tautomeric form, known as a *zwitterion*, in which both the amino and carboxyl groups

are ionized to the same extent. In solutions of aliphatic amino acids, more than 99 per cent of the molecules are present in the form of zwitterions; in the aromatic acids the two forms are present in approximately equal amounts. The addition of acid to the zwitterion suppresses the ionization

of the carboxyl group, thus leaving a positively charged ion which is free to form salts with the acid. Similarly, alkali suppresses the ionization of the amino group, thus leaving a negatively charged ion which can form salts with the base. Thus the effects of adding acid or alkali to the amino

acid are the same regardless of whether the neutral amino acid is considered to be an undissociated molecule or a zwitterion.

These reactions of amino acids with acids and with bases are of great importance in protein chemistry since, as we shall see in Chapter 5, a great many of the physicochemical reactions of proteins are explainable on the basis that the protein molecule contains a definite number of free amino and free carboxyl groups, the exact number of each being characteristic of each particular protein. Depending upon the pH of the solution, therefore, proteins combine with acids and bases, and carry a preponderance of either positive or negative charges, or behave as though they were electrically neutral.

**REACTIONS OF AMINO ACIDS WITH NITROUS ACID.** The amino acids, as their general formula indicates, are primary amines, and like all such amines yield nitrogen when treated with nitrous acid. This reaction

forms the basis for Van Slyke's method for the determination of free amino groups, as has already been indicated. For this purpose use is made of a specially devised apparatus in which the nitrogen gas evolved during the reaction is collected and its volume measured. This reaction is important for the determination of free amino groups in amino acids, or mixtures of amino acids, and is also used in estimating the amounts of amino acids in biological fluids, such as blood. It is also used to determine the percentage of the total nitrogen of the protein that is present in the form of free amino nitrogen. Since the latter increases during acid or enzymatic hydrolysis, the method is also of great value in determining the rate and extent of protein degradation by any of the hydrolytic agents.

**REACTIONS OF AMINO ACIDS WITH NINHYDRIN.** The amino acids in general react with the compound ninhydrin ( $\text{C}_6\text{H}_4 \cdot (\text{CO})_3 \cdot \text{H}_2\text{O}$ , triketohydrindene hydrate) to yield carbon dioxide, ammonia, and usually (but not always) an aldehyde containing one fewer carbon atom than the original amino acid.

This reaction has been made the basis for several different types of quantitative methods for the determination of amino acids. These are based upon (1) the color change which results from the reaction (see pp. 18 and 172), (2) determination of the ammonia produced, and (3) measurement by gasometric means of the carbon dioxide evolved. This latter procedure has been accurately established by Van Slyke and his associates as possibly the most satisfactory method available for the determination of  $\alpha$ -amino nitrogen (in terms of  $\text{CO}_2$ ), exceeding the nitrous acid method

in specificity for this purpose. For a description of this method as applied to the determination of amino acid nitrogen in urine, see p. 892.

REACTIONS OF AMINO ACIDS WITH FORMALDEHYDE. The carboxyl group of the simple amino acids is not readily titratable with alkali under ordinary conditions, presumably because of the influence of the neighboring amino group. In 1899 Schiff observed that in the presence of formaldehyde the amino acids became as readily titratable as any simple organic acid. Sørensen formulated the reaction between amino acids and formaldehyde as follows:

There is considerable evidence against this view, however, and Harris believes that only an amino acid-formaldehyde complex is formed:

Others have suggested that HCHO reacts with amino acids to give mono- or dimethylol derivatives:

The presence of formaldehyde decreases the basicity of the amino group, permitting the carboxyl group to exert its maximum acidity. This acidity may then be titrated with standard sodium hydroxide, using phenolphthalein as indicator. This reaction forms the basis for Sørensen's *formol titration* method for the estimation of free carboxyl groups in amino acids and mixtures of amino acids. It is also widely used for determining the increase in carboxyl groups which accompanies the enzymatic hydrolysis of proteins.

REACTIONS OF AMINO ACIDS WITH AMINO ACIDS. Many of the amino acids readily form anhydrides when their solutions are evaporated. This reaction involves a condensation between the amino group of each molecule with the carboxyl group of the other, the resulting compounds being known as *diketopiperazines*. In 1901 Fischer and Fourneau subjected

glycine anhydride to weak hydrolysis with acids and obtained a compound, glycyl-glycine, in which the amino group of one acid was combined

with the carboxyl group of the other. This was the starting point of a great

many researches whereby Fischer and his co-workers, using various derivatives of amino acids, prepared a large number of similar compounds between amino acids, called *dipeptides*. Although the details of these methods would be out of place in a book of this character, the reactions involved were chosen so that the amino group of one acid always combined with the carboxyl group of the other, resulting in the so-called *peptide linkage*. Since these dipeptides still contained a free amino and a

carboxyl group, by the use of various ingenious methods Fischer was able to lengthen these chains of amino acids, forming polypeptides containing as many as 18 acids. According to the modern conceptions of protein structure, the protein molecule consists in large part, at least, of amino acids linked together through their amino and carboxyl groups. The evidence for this point of view will be discussed more fully in the section on the structure of the protein molecule in Chapter 5.

## DISCUSSION OF THE INDIVIDUAL AMINO ACIDS

**Glycine,  $\text{C}_2\text{H}_5\text{O}_2\text{N}$  (*aminoacetic acid*, *glycocoll*).**

Glycine was the first amino acid to be isolated as a primary decomposition product of the proteins. Glycine is prepared synthetically by the action of ammonia on monochloroacetic acid. It crystallizes in rather large colorless monoclinic crystals usually in four-sided prisms. Glycine possesses no asymmetric carbon atom and is therefore not optically active.

In addition to being present in many animal proteins, glycine is found in the body as a constituent of various nonprotein nitrogenous compounds. It is a component of (1) glutathione, a tripeptide of glutamic acid, cysteine, and glycine (see p. 146); (2) glycocholic acid, a compound

of glycine and cholic acid, found in the bile (see p. 410); and (3) hippuric acid, or benzoyl-glycine, which is found in the urine after the ingestion of benzoic acid or compounds which give rise to benzoic acid in metabo-

FIG. 38. GLYCINE (SYNTHETIC).

See also Fig. 103.

From Keenan: *J. Biol. Chem.*, **62**, 163, (1924).

lism. The reaction leading to the formation of hippuric acid from benzoic acid and glycine is as follows:

## EXPERIMENTS ON GLYCINE

**1. Preparation of Glycine from Hippuric Acid.** Put 5 g. of hippuric acid in a 100-ml. round-bottom flask. Attach the flask to a reflux condenser after adding 20 to 25 ml. of 30 per cent sulfuric acid. Boil the contents of the flask on a wire gauze for one hour, cool under the tap, and filter. The boiling acid splits the hippuric acid into benzoic acid and glycine. The benzoic acid, being quite insoluble in cold acid, begins to crystallize out and is retained on the paper. In order to remove the remainder of the benzoic acid from the filtrate, shake the filtrate with twice its volume of ether in a separatory funnel. The filtrate is next diluted with three volumes of water and heated with sufficient barium carbonate, in the presence of caprylic alcohol to minimize foaming, until the sulfuric acid has been precipitated out as barium sulfate. Remove the barium sulfate by centrifugation and evaporate the filtrate on a water bath until the glycine begins to crystallize out.

**L(+)-Alanine,  $\text{C}_3\text{H}_7\text{O}_2\text{N}$  ( $\alpha$ -aminopropionic acid).**

Alanine is best prepared from silk, in which it occurs to the extent of approximately 25 per cent. It has a sweetish taste, and is dextrorotatory.

FIG. 39. ALANINE.

From Keenan: *J. Biol. Chem.*, **62**, 163 (1924).

**L(—)-Serine,  $C_3H_7O_3N$  ( $\beta$ -hydroxy- $\alpha$ -aminopropionic acid).**

Serine crystallizes from water solution as thin, irregular plates and has a sweet taste. It melts at about  $245^\circ$  and is soluble in 23 times its weight of water at room temperature.

FIG. 40. SERINE.

From Keenan: *J. Biol. Chem.*, **62**, 163, (1924).

**L(—)-Threonine,  $C_4H_9O_3N$  ( $\alpha$ -amino- $\beta$ -hydroxy-n-butyric acid).**

The  $\alpha$  carbon atom of naturally occurring threonine has the L configuration, as shown. When, however, the configuration of the molecule as a whole is considered, it is seen to resemble that of the sugar D-threose (whence the name) so that this amino acid is sometimes referred to as D(—)-threonine.

FIG. 41. THREONINE.

From McCoy, Meyer, and Rose: *J. Biol. Chem.*, **112**, 288 (1935).

**L(+)-Valine,  $C_5H_{11}O_2N$  ( $\alpha$ -aminoisovaleric acid).**

Valine occurs in casein and in egg albumin to the extent of 6 to 7 per cent. It is made synthetically by the interaction of ammonia and  $\alpha$ -bromoisovaleric acid under pressure in which process the bromine is split off as HBr and the amino group takes the  $\alpha$ -position originally occupied by the bromine.

**L(—)-Leucine,  $C_6H_{13}O_2N$  ( $\alpha$ -aminoisocaproic acid).**

Leucine is found in almost all proteins. Free leucine has been found pathologically in urine (in acute yellow atrophy of the liver, phosphorus poisoning, and acute febrile conditions). Pure leucine crystallizes in shiny, white, extremely thin plates. Inactive leucine tastes slightly sweet, D(+)-leucine tastes quite sweet, and L(−)-leucine slightly bitter.

FIG. 42. LEUCINE.

For the material from which the above crystals were prepared, as well as those reproduced in Figs. 43 to 45 and 47 to 48, the authors are indebted to the late Dr. Thomas B. Osborne.

## EXPERIMENTS ON LEUCINE

**Preparation of Leucine.** In a 2-liter flask, place 1 liter of defibrinated blood and gradually add 150 ml. of concentrated sulfuric acid, shaking well during the additions. Boil on a sand bath for 12 to 14 hours, being careful to shake continually until it boils evenly. To the hot liquid add a solution of barium hydroxide until the mixture is alkaline to litmus. Filter on a Buchner funnel. Make the filtrate acid to litmus with dilute  $\text{H}_2\text{SO}_4$ , decolorize with 20 g. of activated charcoal, filter, and concentrate in a porcelain dish over an open flame to 500 ml. and filter again. Make the filtrate faintly alkaline to litmus through the addition of ammonia and concentrate on a boiling water bath until a crystalline mass forms on top of the liquid. Cool for 24 hours in the icebox. Filter on a Buchner funnel and press the water out of the crystals. Recrystallize from 70 per cent alcohol.

Make the following tests upon the leucine crystals already prepared, or upon some pure leucine furnished by the instructor.

1, 2 and 3. Do these experiments according to the directions given for Tyrosine (p. 138).

**L(+)-Isoleucine,  $\text{C}_6\text{H}_{13}\text{O}_2\text{N}$  ( $\beta$ -methyl- $\alpha$ -aminovaleric acid).**

Isoleucine has a bitter taste and it crystallizes in plates like leucine.

**L(—)-Phenylalanine,  $C_9H_{11}O_2N$  ( $\beta$ -phenyl- $\alpha$ -aminopropionic acid).**

Phenylalanine is easily soluble in hot water, quite insoluble in cold water, and only slightly soluble in ethyl and methyl alcohols. It has a bitter taste.

FIG. 43. PHENYLALANINE.

**L(—)-Tyrosine,  $C_9H_{11}O_3N$  ( $\beta$ -parahydroxyphenyl- $\alpha$ -aminopropionic acid).**

Of all the amino acids tyrosine is the least soluble in water (1 part in 2500 of water at room temperature). It is insoluble in ether, alcohol, acetone, and glacial acetic acid, but readily soluble in dilute alkalis and acids. It crystallizes from water in sheathlike groups of fine white needles. Tyrosine is found in most proteins but is virtually absent in gelatin (0.3 per cent). It may be detected in the faintest traces by means of Millon's reaction. (See p. 169.)

### EXPERIMENTS ON TYROSINE

**Preparation of Tyrosine.** Introduce 200 g. of commercial casein into a 3-liter pyrex flask, add a liter of cold water, and shake well. With continuous shaking, slowly add a liter of boiling water to this mixture. Now add 40 ml. of 20 per

cent sodium hydroxide to dissolve the casein, and adjust the reaction of the casein solution to pH 8 by the addition of normal sodium hydroxide.<sup>4</sup>

Preserve the casein solution and diminish oxidase action by adding 15 ml. of toluol and 2 g. of sodium fluoride dissolved in about 10 ml. of hot water. Shake well, add trypsin in the form of some commercial preparation,<sup>5</sup> and, after mixing the contents of the flask thoroughly, stopper the flask and place it in an incubator at 38° to 40°. Shake the flask thoroughly every day, without removing the stopper, and at the end of the fourth day add an addi-

FIG. 44. TYROSINE.

tional quantity of trypsin in one of the forms mentioned. After permitting the digestion to continue for a second period of four days, remove the flask from the incubator, allow it to stand at room temperature for at least 24 hours, then filter off the precipitate of tyrosine, undigested casein, etc. Treat the residue with dilute sulfuric acid (5 ml. of concentrated sulfuric acid in 250 ml. of water) to dissolve the tyrosine, filter through a pleated paper,<sup>6</sup> add 10 ml. of concentrated ammonium hydroxide to the filtrate, and heat on a boiling water bath. The solution, which should now be acid to litmus, is carefully neutralized by the addition of ammonium hydroxide and allow to cool. Tyrosine, contaminated with more or less calcium phosphate, should crystallize out. Filter off the tyrosine by suction, suspend it in 300 ml. of water in a flask, heat to boiling, add 5 ml. of concentrated ammonium hydroxide, and boil for 15 minutes. Filter off the insoluble calcium phosphate, neutralize the tyrosine filtrate with 5 per cent  $\text{H}_2\text{SO}_4$ , and allow it to stand. Filter off the tyrosine crystals by suction, wash well with cold water and alcohol in turn, and dry in an oven or incubator. If the tyrosine crystals are not well formed (see Fig. 44) they may be recrystallized from hot water (solubility 1:154).

<sup>4</sup> To do this take 10 ml. of the casein mixture, add 10 drops of cresol red and titrate with 0.2 N NaOH (using a microburet or a 1-ml. pipet graduated in 0.01 ml.) until a reddish-purple color is obtained. Multiply this titration volume by 40 and add this quantity of normal sodium hydroxide to the casein solution in the pyrex flask. Shake the mixture at frequent intervals after the hydroxide is added. The reaction should now be acid to phenolphthalein and alkaline to cresol red.

<sup>5</sup> If pure trypsin is not available the enzyme may be added in the form of pancreatin.

<sup>6</sup> This filtration can be speeded up by the use of a diatomaceous-earth filter aid.

Make the following tests with the tyrosine crystals prepared in the above experiment, or upon some pure tyrosine furnished by the instructor.

1. *Microscopic Examination.* Place a minute crystal of tyrosine on a slide, add a drop of water, cover with a cover glass, and examine microscopically. Now run more water under the cover glass and warm in a Bunsen flame until the tyrosine has dissolved. Allow the solution to cool slowly, then examine again microscopically, and compare the crystals with those shown in Fig. 44.

2. *Solubility.* Try the solubility of very small amounts of tyrosine in cold and hot water, cold and hot 95 per cent alcohol, dilute  $\text{NH}_4\text{OH}$ , dilute  $\text{KOH}$ , and dilute  $\text{HCl}$ .

3. *Sublimation.* Place a little tyrosine in a dry test tube, heat gently, and notice that the material does not sublime. How does this compare with leucine?

4. *Hofmann's Reaction.* This is the name given to Millon's reaction when employed to detect tyrosine. Add about 3 ml. of water and a few drops (avoid an excess) of Millon's reagent to a little tyrosine in a test tube. Upon dissolving the tyrosine by heat the solution gradually darkens and may assume a dark-red color. What group does this test show to be present in tyrosine?

5. *Sulfuric Acid Test (Piria).* Warm a little tyrosine on a watch glass on a boiling water bath for 20 minutes with 3 to 5 drops of concentrated  $\text{H}_2\text{SO}_4$ . Tyrosine-sulfuric acid is formed in the process. Cool the solution and wash it into a small beaker with water. Now slowly add  $\text{CaCO}_3$  in substance with stirring, until the reaction of the solution is no longer acid. Filter, concentrate the filtrate, and add it to a few drops (avoid an excess) of very dilute neutral ferric chloride. A purple or violet color, due to the formation of the ferric salt of tyrosine-sulfuric acid, is produced. This is one of the most satisfactory tests for the identification of tyrosine.

6. *Formaldehyde-Sulfuric Acid Test (Mörner).* Add about 3 ml. of Mörner's reagent<sup>7</sup> to a little tyrosine in a test tube, and gently raise the temperature to the boiling point. A green color results.

7. *Folin's Test.* To 1 to 2 ml. of the solution to be tested add an equal volume of "phenol reagent" (the Folin-Ciocalteu modification<sup>8</sup> is satisfactory) and 3 to 10 ml. of a saturated solution of sodium carbonate. A blue color is given by tyrosine. The reaction has a sensitivity of one part in one million. Tryptophan also gives this reaction.

**L-Diiodotyrosine and L-Thyroxine.** When tyrosine or a protein containing tyrosine is incubated at  $37^\circ$  with sodium bicarbonate and iodine, both diiodotyrosine and thyroxine are formed.

---

<sup>7</sup> Mörner's reagent is prepared by thoroughly mixing 1 ml. of formalin, 45 ml. of distilled water, and 55 ml. of concentrated sulfuric acid.

<sup>8</sup> See Appendix.

**L(—)-Cysteine,  $\text{C}_3\text{H}_7\text{O}_2\text{NS}$  ( $\beta$ -thiol- $\alpha$ -aminopropionic acid).**

This amino acid is recognized as being present as such in the intact protein molecule but it is not ordinarily obtained as one of the products

FIG. 45. CYSTINE.

of protein hydrolysis unless precautions are taken against oxidation, since it is readily converted by oxidation of the —SH group into various sulfinic and sulfonic acids and into cystine. The relation between cysteine and cystine may be illustrated as follows:

This reversible oxidation-reduction reaction involving the sulfhydryl group (—SH) appears to have considerable physiological significance. Thus it accounts for the oxidation and reduction reactions of glutathione,

which contains cysteine, and it appears that adjacent polypeptide chains in the protein molecule are linked together through the oxidation of cysteine sulfhydryl groups. Experiments on cysteine have been grouped with those on cystine.

**L(—)-Cystine,  $C_6H_{12}O_4N_2S_2$  (*di*( $\beta$ -thiol- $\alpha$ -aminopropionic acid)).**

Cystine is obtained in greatest amount as a product of the hydrolysis of keratin-containing tissue such as horn, hoof, feather, and hair. It crystallizes in characteristic hexagonal plates which are only very slightly soluble in cold water and in alcohol. It dissolves readily in mineral acids or in alkalis but it is insoluble in acetic acid.

## EXPERIMENTS ON CYSTINE AND CYSTEINE

**Preparation of Cysteine by the Cuprous Oxide Method (after Lucas and Beveridge).** Place 300 g. of human hair (barbershop sweepings) in a 2.5-liter flask, and pour in 500 ml. of ether. Boil under a reflux condenser on a water bath for a few minutes to dissolve the oil and fat on the hair. Pour off the ether, and to the hair add 1600 ml. of 9N HCl. Boil the solution under reflux for 11 hours. Concentrate the solution in vacuo to remove excess HCl, then dissolve the residue in hot water and filter off the humin. Wash the precipitate with dilute HCl. Concentrate the filtrate and washings to a thick syrup. Take up the residue in hot water and again concentrate, this time to dryness. Repeat this process twice more. Dissolve the final residue in 1200 ml. of water.

Grind the amino acid solution with 300 g. of red cuprous oxide in a mortar for 30 minutes. Then slowly add the suspension with stirring to 12 liters of ice water. Cool at 4° C. for 2 hours. Filter the grayish-white cysteine copper mercaptide and wash the precipitate with ice water.

Suspend the mercaptide in water and remove the copper by passing in a stream of  $H_2S$ . Filter off the copper sulfide, washing the residue with dilute HCl. Concentrate the filtrate and washings to 500 ml., then decolorize by boiling with 3 g. of charcoal and filtering. Concentrate the filtrate in vacuo under a stream of nitrogen to incipient crystallization. Cool in the refrigerator. An almost solid mass of cysteine hydrochloride should form. Filter off the crystals and wash with cold concentrated HCl.

**Preparation of Cystine by Schmidt's Method.** Human hair or wool which has been freed from oil by extraction with gasoline is hydrolyzed by heating at 100° C. with twice its weight of concentrated HCl. It requires about 12 hours to effect complete hydrolysis. The mixture must not be heated for any length of time beyond the point at which the biuret test is either negative or feebly positive since cystine is destroyed during the process of hydrolyzing

the protein. The greater part of the hydrochloric acid is removed by distilling in vacuo at a temperature between 60° to 70° C. and the original volume of the solution is restored by the addition of water. A thick aqueous suspension of commercial finishing lime is now slowly added, care being taken to avoid any considerable rise in temperature, until the mixture has acquired a chocolate color. It is then filtered by suction through a Buchner funnel and the residue washed a number of times with distilled water. The filtrate should be clear and possess a light brown color. Hydrochloric acid is now added to partially neutralize the alkaline solution and it is finally acidified by addition of acetic acid. On standing over night in the icebox, sedimentation of the crude cystine takes place. This is filtered off and is dissolved in a minimum quantity of 5 per cent HCl. The solution is decolorized by boiling for several minutes with a small quantity of charcoal which has been previously boiled with HCl to remove the calcium phosphate, and the cystine is precipitated by the addition of sodium acetate to the hot solution until a drop of the solution ceases to turn Congo-red paper blue. The mixture is filtered at once and the cystine is washed a number of times with hot water to completely remove the last traces of tyrosine. Typical hexagonal plates of cystine are obtained. (See Fig. 45.)

### *Tests for Cystine and Cysteine.*

#### (a) SULLIVAN'S TESTS.

*Cystine.* To 5 ml. of the solution under test (containing not more than 0.04 per cent of cystine in approximately 0.1 N hydrochloric acid, at a temperature of about 25° C.) add 1 or 2 ml. of freshly made 5 per cent aqueous solution of sodium cyanide. Mix and let stand 10 minutes. Then add 1 ml. of a freshly prepared 0.5 per cent solution of 1,2-naphthoquinone-4-sodium sulfonate, sodium sulfite, etc., as given below for cysteine.

*Cysteine.* To 5 ml. of solution containing not more than 0.04 per cent of cysteine in 0.1 N hydrochloric acid, add 1 ml. of 1 per cent sodium cyanide in 0.8 N sodium hydroxide. Mix and add 1 ml. of a freshly prepared 0.5 per cent aqueous solution of 1,2-naphthoquinone-4-sodium sulfonate. Mix and add 5 ml. of 10 to 20 per cent solution of anhydrous sodium sulfite in 0.5 N sodium hydroxide. Mix and let stand 30 minutes. A reddish-brown color appears. Then add 1 ml. of a 2 per cent solution of sodium hyposulfite ( $\text{Na}_2\text{S}_2\text{O}_4$ ) in 0.5 N sodium hydroxide. The brown-red color in the presence of cysteine (or cystine treated with sodium cyanide) is converted to a purer red.<sup>9</sup>

(b) TESTS FOR SULFHYDRYL (SH) GROUP. On the addition of a dilute solution of  $\text{FeCl}_3$ , an indigo-blue color appears and disappears almost immediately. Add a dilute solution of  $\text{CuSO}_4$ , whereupon a transitory violet color appears.

Test 1 or 2 ml. of cysteine solution with a dilute solution of sodium nitroprusside and a drop of NaOH. A deep purple-violet color appears but gradually fades after a few minutes.

Add a few drops of a 10 per cent aqueous solution of lead acetate to the cystine (or cysteine) solution, then render the solution strongly alkaline with 40 per cent NaOH or KOH. Boil for a few minutes. If cystine or cysteine are present, the solution becomes brown and a black precipitate of PbS appears (lead-blackening test).

<sup>9</sup> The reaction requires a high final pH. In case of hydrolyzates of foodstuffs it is necessary to add 1 or 2 ml. of 5 N sodium hydroxide just before adding the final reducing agent, sodium hyposulfite ( $\text{Na}_2\text{S}_2\text{O}_4$ ). As a rule it is cystine that is found in hydrolyzates.

**L(—)-Methionine**,  $C_5H_{11}O_2NS$  ( $\gamma$ -*methythiol- $\alpha$ -amino-n-butyric acid*).

When methionine is treated with concentrated sulfuric acid, the methyl group is split off and the amino acid homocysteine is ultimately obtained.

Homocysteine is similar to cysteine in many ways, and its formation and quantitative determination may be used for the quantitative determination of methionine. While homocysteine has not as yet been isolated from proteins, there is good evidence that it is an intermediate in the biological transformation of methionine into cystine (see p. 1030).

### EXPERIMENT ON METHIONINE

*Methionine can be detected in a mixture of amino acids by the following method (Bolling's modification of McCarthy-Sullivan).* To 7.5 ml. of unknown, add the following reagents in order, mixing after each addition: 1.5 ml. of 5 N NaOH, 1.5 ml. of 1 per cent glycine, and 0.3 ml. of 10 per cent sodium nitroprusside (freshly prepared). Place the tube in a water bath at 37° to 40° C. for 15 minutes, cool in ice water for 5 to 7 minutes, and add 3 ml. of 6 N HCl. Shake for 1 minute and let stand at room temperature for 15 minutes. A reddish-purple color indicates methionine. Tryptophan interferes.

**L(—)-Tryptophan**,  $C_{11}H_{12}O_2N_2$  ( $\beta$ -3-*indole- $\alpha$ -aminopropionic acid*).

The natural levorotatory compound is best prepared by the prolonged action of trypsin on casein (see p. 398). Tryptophan is present in nearly all proteins, but is absent from gelatin and zein.

### EXPERIMENTS ON TRYPTOPHAN

**Color Reactions for Tryptophan.** (a) **HOPKINS-COLE TEST.** If a substance containing this amino acid is placed in a test tube, a solution containing a

small amount of glyoxylic acid added, and sulfuric acid then stratified on the bottom of the tube, a reddish-violet ring will appear at the juncture of the two liquids. This is also known as the glyoxylic acid test (see p. 170). Pure tryptophan will not give this test except in the presence of a trace of ferric or cupric ions.

(b) ALDEHYDE REACTION (VOISENET-RHODE). Tryptophan will also give color reactions in the presence of aromatic aldehydes. With *p*-dimethylamino-benzaldehyde in sulfuric acid it gives a red-violet color. These color reactions are apparently due to the presence of the indole ring in tryptophan. The indole

FIG. 46. TRYPTOPHAN.

From Keenan: *J. Biol. Chem.*, 62, 163 (1924).

ring, being a combination of the benzene and pyrrole rings, probably owes its chromogenic properties to the latter ring. For other tryptophan reactions see Chapter 16.

**L(—)-Proline**,  $C_5H_9O_2N$  (*pyrrolidine-2-carboxylic acid*).

Proline is easily soluble in alcohol and in cold water. It has a sweet taste and melts at  $153^\circ$  to  $154^\circ$ .

**L(—)-Hydroxyproline**  $C_5H_9O_3N$  (*4-hydroxy-pyrrolidine-2-carboxylic acid*).

It is very difficult to separate hydroxyproline from the other amino acids. It is easily soluble in water and soluble with difficulty in absolute alcohol.

FIG. 47. PROLINE.

L(—)-Aspartic acid,  $C_4H_7O_4N$  ( $\alpha$ -aminosuccinic acid).

This amino acid, unlike the others thus far considered, is strongly acidic on account of the predominance of the carboxyl group. The chief source

FIG. 48. ASPARTIC ACID.

of this acid is the monoamide, asparagine, which is very widely distributed in the vegetable world, being particularly abundant in the asparagus plant and in lentil sprouts. It is more than likely that the amide (aspara-

gine) rather than aspartic acid occurs in the protein molecule, but is quickly hydrolyzed into aspartic acid and ammonia during the process of protein cleavage.

**L(+)-Glutamic acid,  $\text{C}_5\text{H}_9\text{O}_4\text{N}$  ( $\alpha$ -aminoglutaric acid).**

This acid, when obtained after the hydrolysis of the protein molecule, is largely a secondary product. The primary constituent of the protein molecule is undoubtedly glutamine, the amide of glutamic acid, which accounts for the greatest part of the total glutamic acid found after hydrolysis of the protein. Glutamic acid is present in practically all proteins,

usually in fairly large amounts, being present to the extent of 47 per cent in gliadin, a protein found in wheat, and to the extent of 23.3 per cent in casein. The sodium salt of glutamic acid is widely used commercially for flavoring soups, sauces, and food concentrates.

Glutamic acid is found combined with glycine and cysteine in the

glutathione molecule (see p. 321). Glutathione has been shown to be a tripeptide, having the following structure:

Attention is called to the fact that the glutamic acid is linked to the amino group of cysteine through its  $\gamma$  carboxyl group.

FIG. 49. GLUTAMIC ACID.

Reproduced from a photomicrograph made by Prof. E. T. Reichert, of the University of Pennsylvania.

## EXPERIMENTS ON GLUTAMIC ACID

**Preparation of Glutamic Acid.** In a 500-ml. flask place 100 g. of gluten flour and 300 ml. of concentrated HCl. Heat on a water bath until the gluten has dissolved. Boil under a reflux condenser for 8 hours on a wire gauze. Cool, dilute with an equal volume of water, and filter. Evaporate to about one-fourth the volume in vacuo. Transfer the residue to a 250-ml. Erlenmeyer flask and saturate with HCl gas, then cool, seed, and place in the icebox for 2 to 3 days. By this time crystals of glutamic acid hydrochloride should have formed. Add an equal volume of ice-cold acetone and filter through a sintered glass funnel. Instead of recrystallizing the crystals, wash in the funnel with ice-cold acetone and ether.

In order to prepare the free glutamic acid from the glutamic acid hydrochloride, dissolve the crystals in the least possible amount of hot water, and then add normal alkali until the solution no longer gives a blue coloration with Congo red, pH 3.2-3.3. Evaporate the solution to 60 ml. in vacuo at 40°. Allow this solution to remain in the icebox until crystallization is complete. Filter off the crystals, wash with a little cold water, and dry. Determine the melting point of the crystals. Examine microscopically (see Fig. 49).

**L(—)-Histidine,  $C_6H_9O_2N_3$**  ( *$\beta$ -imidazole- $\alpha$ -aminopropionic acid*).

Histidine is found in small quantities in practically all proteins, but is present to the extent of 8 per cent in hemoglobin. It combines with a variety of substances, forming, for example, mono- and dihydrochlorides, also compounds or double salts with platinum chloride or silver nitrate which are particularly valuable for obtaining a pure crystalline com-

FIG. 50. HISTIDINE DIHYDROCHLORIDE.

pound. It also forms characteristic compounds with picric acid, phosphotungstic acid, nitrobenzoyl chloride, 2,5-dichlorobenzene sulfonic acid, nitranilic acid, etc.

**L(+)-Arginine,  $C_6H_{14}O_2N_4$**  ( *$\delta$ -guanidino- $\alpha$ -aminovaleric acid*).

Arginine is present in all tissue proteins. It is hydrolyzed into urea and the amino acid ornithine ( $\alpha, \delta$ -diaminovaleric acid) by the enzyme arginase which is found in the liver.

This reaction is thought to be of major importance in connection with the formation of urea by the body (see Chapter 33 for a discussion of this and other metabolic relationships of arginine).

## EXPERIMENTS ON ARGININE

**1. Isolation of Arginine Flavianate (Kossel).** Hydrolyze a 25-g. portion of gelatin by boiling with 250 ml. of 18 per cent hydrochloric acid under reflux for 18 hours. Remove the excess acid by repeated concentration in vacuo. Take up the residue in 250 ml. of hot water and decolorize with 5 g. of charcoal. Bring the filtrate to a volume of 250 ml. and add a saturated aqueous solution containing 200 g. of flavianic acid (2,4-dinitro-1-naphthol-7-sulfonic acid) at room temperature. Allow the precipitate to form in the cold for 5 days, stirring from time to time. Filter off the yellow precipitate and wash with a little cold water. Dissolve the washed precipitate in hot water with the aid of a minimal quantity of 4 per cent ammonia. While the solution is still hot add sufficient 20 per cent hydrochloric acid to neutralize all the ammonia. Arginine flavianate crystallizes in shining yellow plates from the hot solution.

**L(+)-Lysine,  $\text{C}_6\text{H}_{14}\text{O}_2\text{N}_2$  ( $\alpha$ - $\epsilon$ -diaminocaproic acid).**

Lysine is one of the basic amino acids, possessing a predominance of amino groups over acidic or carboxyl groups. Histidine, arginine, and lysine have been called "the hexone bases." Lysine is present in most proteins of animal origin. It is notably absent from zein and present in rather small amounts in gliadin.

FIG. 51. LYSINE PICRATE.

**Citrulline,  $C_6H_{13}O_3N_3$**  ( $\delta$ -*carbamino*- $\alpha$ -*aminovaleric acid*).

Citrulline was obtained by Wada in 1930 from watermelon juice. Little is known concerning its distribution in proteins. Free citrulline is present in small amounts in liver and in blood. Interest in citrulline at the present time is based largely upon its relation to arginine and the processes of urea formation in the animal body (see Chapter 33).

**Newer Amino Acids.** The application of newer research techniques such as paper chromatography for the isolation and identification of amino acids in hydrolyzates, and the use of microorganisms as nutritional test subjects, have led to the discovery of a number of amino acids and related compounds not hitherto identified among the products of protein hydrolysis. Among those of biological interest, mention may be made of:

**$\alpha$ -Aminobutyric acid** found in the brain and central nervous system, where it is formed by decarboxylation of glutamic acid.<sup>10</sup> It has also been shown to be produced enzymatically from DL-threonine.<sup>11</sup>

**Lanthionine** (THIODIALANINE) from wool;<sup>12</sup>

**Cystathionine**, a condensation product of homocysteine and serine intermediate in the synthesis of cysteine;<sup>13</sup>

**Ergothioneine**, found in ergot, blood (1.8–1.95 mg. per 100 ml. in human blood),<sup>14</sup> and in the seminal plasma of the boar;<sup>15</sup>

<sup>10</sup> Roberts and Frankel: *J. Biol. Chem.*, **187**, 55 (1950); **188**, 789 (1951); **190**, 505 (1951).

## Proteins: Their Structure and General Reactions

The results of investigations on the hydrolysis of proteins indicate that the protein molecule is composed almost exclusively, if not entirely, of  $\alpha$ -amino acids. Investigations of this type, which involve the complete tearing down of the protein molecule, yield the constituent amino acids but throw practically no light on the question as to the order in which these acids are linked together to form the intact protein molecule with its characteristic chemical, physicochemical, colloidal, and biological properties. In spite of this defect these researches are of the highest importance since they yield the actual "building stones" of the protein molecule.

In recent years emphasis has been placed on the study of the physicochemical behavior of the intact protein. The difficulty involved in the formulation of an acceptable theory for the structure of the protein molecule becomes apparent when we list the great number and variety of properties and reactions of proteins that such a theory is called upon to explain. Of these, we may mention especially the following: (1) The hydrolysis of proteins by acids, alkalies, and proteolytic enzymes into their constituent amino acids; (2) the small proportions of free amino and carboxyl groups in the intact molecule; (3) the large increase in both amino and carboxyl groups that accompanies the hydrolysis of the protein; (4) the combinations of proteins with acids, bases, and many other classes of compounds; (5) the large size and colloidal nature of the protein molecule, together with the complex colloidal behavior of protein solutions; (6) the complex solubility relationships of the various classes of proteins; (7) the sensitiveness of proteins to chemical and physical agents such as acids, alkalies, alcohol, heat, mechanical shaking, ultraviolet light, etc.; (8) the immunological reactions of the proteins; and (9) their highly specific enzymatic, hormonal, and other biological properties. In the following sections the modern conceptions of protein structure will be discussed briefly together with the more important reactions and properties of proteins which make them such vital constituents of living protoplasm.

**Structure of Protein Molecule: Peptide Linkage.** It was pointed out by Hofmeister, in 1902, that there are three conceivable types of linkage by which individual amino acids might be joined together in the protein molecule.

The first type of linkage involves direct union between carbon atoms:

This type of union is very unlikely since bonds between carbon atoms are not attacked by proteolytic enzymes which hydrolyze native proteins. It is difficult, also, to understand how a molecule having such a structure could be broken down by hydrolytic agents into such definite structural units as the polypeptides and amino acids.

The second type of linkage that suggests itself is a linkage of carbon atoms by means of an oxygen atom, as in the ethers, esters, and anhydrides:

This type of union is also improbable since, in view of the number of its carboxyl groups, the protein molecule does not contain sufficient oxygen to account for a major linkage of that kind. Moreover, since such a linkage does not involve the amino groups, the latter should be much more abundant in the intact protein molecule than they actually are.

This leaves, as the final possibility, the linkage of carbon atoms by means of a nitrogen atom:

Of the various possibilities for such a linkage, that resulting from the condensation of the amino group of one acid with the carboxyl group of another, which Fischer named the *peptide linkage*, is the only one which is in accord with the experimental facts. Fischer devised several ingenious methods for condensing amino acids in this manner and prepared a large number of di-, tri-, and polypeptides, some of them containing as many as 18 molecules of amino acids. Many of the synthetic polypeptides prepared by Fischer, Bergmann, and others are identical with polypeptides isolated from partially hydrolyzed proteins.

According to modern conceptions of protein structure the peptide bond is the predominant bond in the protein molecule. This point of view is based on a great mass of experimental evidence, of which only a brief review may be given here. The structural formula of the tetrapeptide given below indicates clearly that only those amino and carboxyl groups which are at the ends of chains are free. When the molecule contains diamino or dicarboxylic acids, the additional amino or carboxyl groups

either may remain free or may be the starting points for side chains of various kinds. Analyses of proteins indicate that the number of free amino and carboxyl groups in the intact molecule, determined by Van Slyke's nitrous acid and Sørensen's formol titration methods, is substantially what would be expected of a molecule built up of amino acids joined together by means of peptide linkages. Furthermore, hydrolysis of proteins by acids or enzymes results in the liberation of equal numbers of amino and carboxyl groups, such as would arise during the hydrolysis of peptide bonds. The biuret reaction, which is characteristic of proteins and some of their decomposition products, is given by many of the synthetic polypeptides and practically disappears when all these substances are completely hydrolyzed.

**Relation of Structure to Properties of Proteins.** The generally accepted theory of Hofmeister and Fischer that proteins consist of chains of amino acids joined to each other through their amino and carboxyl groups does not by itself seem to explain the unique chemical, physical, and biological differences among proteins in nature. Why are keratins so resistant to dilute acids and proteolytic enzymes? How does the muscle protein, myosin, function in the contraction of muscle? What is responsible for the immunological specificity of proteins, for the enzyme action of catalase and pepsin, for the toxicity of tobacco mosaic virus, and so forth? The hypotheses which are mentioned briefly below are attempts to answer some of these questions.

A. PROTAMINE NUCLEUS HYPOTHESIS OF KOSSEL AND SIEGFRIED. These investigators believed that all proteins were built around a nucleus of the three amino acids arginine, histidine, and lysine, and that arginine was the most important member of this triad. Block has shown that one group of proteins, eukeratins, can be characterized by the relative constancy of the ratios of arginine to lysine to histidine. The location of these three amino acids or their mode of action in the formation of the eukeratins remains unknown. It should also be pointed out that no protein devoid of arginine has as yet been reported, although some large peptides are lacking in this amino acid.

B. DIKETOPIPERAZINE HYPOTHESIS OF ABDERHALDEN. Amino acid anhydrides (diketopiperazines, see p. 130) can be obtained from proteins under certain conditions. These compounds are readily formed by condensation of two amino acids or by cyclizing a dipeptide. Abderhalden suggested that proteins are composed of diketopiperazine-containing units which are held together by secondary valences. This structure was intended to account for certain properties of proteins, especially the hydrolysis to peptones by pepsin. Unfortunately for this theory, amino acid anhydrides are not hydrolyzed by proteolytic enzymes.

C. STEREOCHEMICAL ORGANIZATION OF THE PROTEIN MOLECULE (FOA, MEYER AND MARK, ASTBURY, NEURATH, WRINCH, PAULING). The use of the x-ray to study the fine structure of proteins, especially in the hands of W. T. Astbury, has given us a much clearer insight into the organization of the peptide chains in the protein molecule. A short section of such a chain in the fully extended position is shown in Fig. 52. In general these peptide chains are pictured as either fully extended (silk fibroin, or other

denatured, mechanically elongated fibrous proteins) or folded chains of (native) insoluble fibrous and soluble globular proteins. In certain cases, such as hair and wool, the long axis of the peptide chain is parallel to the long axis of the fiber, and the strength, elasticity, and resistance to enzymatic hydrolysis can be definitely correlated to this structure. Thus hair keratin can be pictured as consisting of bundles of partially folded peptide chains which are cross-linked to each other through the —S—S— bonds of cystine. The tensile strength of hair is thus explained by the

FIG. 52. SCALED MODEL OF A FULLY EXTENDED POLYPEPTIDE CHAIN, VIEWED FROM ABOVE.

Neurath: *J. Phys. Chem.*, **44**, 297 (1940).

large number of similar peptide chains in parallel; the elasticity by the folding and unfolding of the chains; and the resistance to enzymes by the close packing of the parallel chains.

The structure of the soluble proteins, especially those whose molecules are essentially oval or globular in shape, is still largely unexplained, although the speculations of Wrinch and others concerning cagelike, spiral, or multiple-discoid structures may be the clues to their ultimate solution.

As mentioned above, it has long been clear that the properties of native proteins cannot be explained solely on the hypothesis that they are formulated as straightforward peptide chains joined by disulfide and other cross linkages (cf. below). Closely similar x-ray diffraction patterns characteristic of  $\alpha$ -keratin,  $\beta$ -keratin, and collagen are given by proteins of very different amino acid composition. Thus, it is evident that there must be some regularity of structure of proteins which is independent of the amino-acid side chains and must arise from the coiling or folding of the peptide chains themselves. A number of structures have been proposed to

FIG. 53. THE HELIX WITH 3.7 RESIDUES PER TURN.

account for these distinctive x-ray patterns, all of which suffer from the disadvantage of not meeting all the experimental evidence. In 1951, Linus Pauling and his co-workers, Corey and Branson, employing as sole restrictions to their formulation the accepted interatomic distances and covalency angles, the planarity of the amide groups, and the linearity of the  $\text{—N—H—O—}$  hydrogen bond and assuming that the maximum possible number of intramolecular hydrogen bonds would be formed, arrived at certain helical structures.<sup>1</sup> One of these gave 3.7 amino acid residues per complete helical turn. This resulted in 13-membered rings, closed by  $\text{—CO—}$  and  $\text{—NH—}$  groups in hydrogen-bond linkage as shown in perspective and in plan (Figs. 53 and 54, respectively). This so-called  $\alpha$ -helix has been rather definitely established to occur in hair, horn, and other proteins of the  $\alpha$ -keratin class (including muscle) as well as in hemoglobin and many other globular proteins such as serum albumin, insulin, lysozyme, and chymotrypsin. Another proposed helical formation, the  $\gamma$ - or 5.1-residue helix, is now believed to be too unstable to exist in proteins. However, an "antiparallel-chain pleated sheet" structure<sup>1a</sup> appears to be characteristic of silk and stretched hair.

It is generally believed that the gamma globulin of blood is able to assume different shapes under the impact of foreign antigens while retaining its amino acid composition and arrangement unmodified. It seemed that too rigid specification of the peptide (backbone) coiling of gamma globulin would be incompatible with its known lability with respect to the formation of antibodies. The 3.7 amino-acids-residue helix seems capable of overcoming this difficulty since it may be transposed into many different patterns by starting the helix with the same amino acid but at geometri-

FIG. 54. PLAN OF THE 3.7-RESIDUE HELIX.

<sup>1</sup> Pauling, Corey, and Branson: *Proc. Natl. Acad. Sci.*, 37, 207 (1951) and personal communication.

<sup>1a</sup> Pauling and Corey: *Proc. Natl. Acad. Sci.*, 37, 729 (1951).

cally different points. To visualize the 3.7 helix better, it may be compared to a spiral staircase with each amino acid residue as a step. The height of each step is  $1.5 \text{ \AA}$  and the height of each turn is  $5.4 \text{ \AA}$  making 3.6 or 3.7 steps per turn. It thus takes 18 steps or 5 turns for a step to be found exactly in a vertical line above the starting point.

The closely knit structure of highly organized soluble globular proteins is broken down by denaturing agents such as strong sodium hydroxide. The peptide chains then become a mass of disorganized fibrils in solution. If this alkaline protein solution is passed through a small capillary, these fibrils orient themselves with their long axes parallel to the direction of flow. If the alkaline solution is then extruded through a small orifice into an acid or other coagulating bath, the protein fibrils unite with each other parallel to their long axes and a typical macroscopic thread is formed. This is the essence of the production of synthetic fiber, "wool," etc., from soluble globular proteins such as casein and soybean.

The three main types of cross linkage in proteins appear to be (1) Dithio bridges formed by cystine, (2) Salt bridges formed by the carboxyl groups of aspartic or glutamic acid and by amino groups of lysine or guanido groups of arginine, and (3) Hydrogen bonds between peptide linkages and between polar groups of the amino acids:

From this presentation it is apparent that the solution to the problems of protein structure and function has not yet been found, but that the Hofmeister-Fischer peptide theory, coupled with the known electrical and chemical properties of the peptide linkage ( $-\text{NH}-\text{CO}-\text{CHR}-$ ) and of the specific side chains of the amino acids, offers a reasonable basis to account for many of the properties of natural and of isolated proteins.

**Proteolytic Enzymes.** The most convincing evidence that the peptide linkage is the principal type in the protein molecule comes from the fact that enzymes are able to hydrolyze synthetic polypeptides of known structure, liberating equal amounts of amino and carboxyl groups, just as they do when acting on native proteins. Our knowledge on the structural specificity of enzymes is due in large part to the brilliant researches of Bergmann and his co-workers. The table given below illustrates the specificity of enzymes.

ACTION OF PROTEOLYTIC ENZYMES (BERGMANN)

| <i>Enzyme</i>                                         | <i>Requisite Peptide Chain</i>                                                                                                                                                                                                       | <i>Requisite Amino Acid in Peptide Chain</i> |
|-------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------|

| Leucyl amino-peptidase<br>(Cathepsin III)             | $  \begin{array}{c}  \text{R} \\    \\  \text{H}_2\text{N---CH---CO---NH---} \\    \qquad \text{HO} \quad   \\  \downarrow \qquad \text{H} \\  \text{R}  \end{array}  $ $  \text{H}_2\text{N---CH---COOH} + \text{H}_2\text{N---}  $ | Leucine                                      |
| Carboxypeptidase<br>(Cathepsin IV)                    | $  \begin{array}{c}  \text{R} \\    \\  \text{---CO---NH---CH---COOH} \\    \qquad \text{HO} \quad   \\  \text{H} \qquad \downarrow \\  \qquad \text{R}  \end{array}  $ $  \text{---COOH} + \text{H}_2\text{N---CH---COOH}  $        | Tyrosine or Phenylalanine                    |

Up to the time of these investigations it was believed that the size and not the amino acid composition of the protein or polypeptide was the controlling factor in enzymatic breakdown. Thus pepsin was thought to act on proteins of high molecular weight such as fibrin, casein, etc., but not on the smaller protamines, while trypsin split the smaller molecules, such as the protamines, and erepsin hydrolyzed peptides of still lower molecular weight. It is now evident that pepsin fails to hydrolyze protamines not because of their molecular size but because these proteins are

deficient in tyrosine and phenylalanine, while the ample supply of arginine and lysine in protamines permits the action of trypsin. Likewise a mixture of polypeptides containing a relatively high proportion of free carboxyl groups would be split by carboxypeptidases (erepsin?) such as the "aromatic" carboxypeptidase shown in the table above. In each case, *the ratio of carboxyl to amino groups liberated is unity*. The resistance of certain proteins, such as silk fibroin, hair keratin, etc., to digestion by proteolytic enzymes is not explainable on the basis of amino acid composition but is due to the close packing of the protein molecules, which then offer relatively little surface to the enzyme. If the molecular structure is disorganized by mechanical or chemical means, these proteins are readily hydrolyzed by the proteolytic enzymes.

In the current hypothesis of enzyme action it is assumed that the enzyme-substrate complex is formed by the bonding of complementary surfaces. Thus the mechanism would depend primarily on the steric arrangement of the molecular groups of the substrate, their shape and mutual positions, and only secondarily on the chemical nature of the bond undergoing hydrolysis.

**The Composition of Insulin.** In spite of all the chemical and physico-chemical studies on many proteins, only one protein has been so thoroughly investigated that its amino acid sequence is completely known. In a series of brilliant researches, Sanger and his co-workers at Cambridge, England, have elucidated the chemical structure of pure, crystalline insulin. In brief, they broke the —SS— bonds which hold the peptides of insulin, by oxidation with performic acid. This procedure not only breaks the —SS— bonds but also oxidizes the cysteine residues to cysteic acid residues. The resulting oxidized insulin was then separated into two fractions: fraction A contained only glycine at the amino end of the chain; fraction B contained only phenylalanine as the N-terminal amino acid. These two fractions were then subjected to partial hydrolysis by dilute acid or by enzymes. When the hydrolytic products (amino acids and small peptides) were separated and identified by means of paper chromatography, Sanger, Thompson, and Tuppy were able to fit these together to give the exact sequence of all the amino acids in each of the peptides. Their results are given in the accompanying table.

**Molecular Weights of Proteins.** Many of the properties of protein solutions, especially those connected with their colloidal behavior, are intimately related to the size and molecular weight of the protein. The determination of the molecular weights of the proteins involves many difficulties owing to the complex solubilities of the proteins and the colloidal nature of their solutions. Thus, for example, the ordinary physico-chemical methods, such as the raising of the boiling point or lowering of the freezing point, are either inapplicable or yield misleading results when applied to proteins because of the effects of traces of salts and other impurities on determinations made by those methods. However, the minimal molecular weight can be obtained from chemical, especially amino acid, analyses. By assuming that the protein molecule contains one atom of an element or one molecule of the amino acid present in least amount,

\* The cysteic acid exists in the insulin molecule as cystine.

the minimal molecular weight may be calculated from the following relationship:

Minimal molecular weight of protein

$$\begin{aligned} &= 100 \times \frac{\text{Atomic weight of element}}{\text{Percentage of element}} \\ &= 100 \times \frac{\text{Molecular weight of amino acid}}{\text{Percentage of amino acid in protein}} \end{aligned}$$

On the other hand the relatively large particle size of most proteins has permitted the development of methods for estimating their size and molecular weight which could not be used for the average organic compound. These are:

1. Molecular weight from osmotic pressure (Sørensen, Roche, Adair, Greenberg, et al.).

2. Molecular weight from sedimentation equilibrium and from sedimentation rate and diffusion (Svedberg, Peterson).

3. Molecular weight from diffusion and viscosity (Northrop and Anson, Neurath, et al.).

4. Molecular size and shape from dielectric-constant dispersion curves (Williams, Oncley).

5. Molecular size from x-ray diffraction data (Crowfoot, Fankuchen).

The osmotic-pressure method yields the mean molecular weight when carried out under suitable experimental conditions. This procedure, which can be carried out with ordinary laboratory equipment, suffers from the disadvantages that it gives no indication of homogeneity of the substance investigated and that it becomes increasingly insensitive with increasing molecular weights.

Every molecule in solution is subject to thermal forces which result in diffusion of the substance away from a center of high concentration toward one of lower concentration. In addition to these thermal forces the molecule is subject to gravitational forces which tend to cause the molecules to sediment. It is thus apparent that whether a substance will remain in solution or not is dependent upon the relative strengths of the gravitational (settling) and thermal diffusion forces. By increasing the speeds attainable in the ordinary laboratory centrifuge, Svedberg, Beams, and others have constructed very high-speed centrifuges (ultracentrifuges) which are able either just to balance the diffusion forces of a protein molecule in solution (sedimentation equilibrium) or actually overcome these thermal forces and cause the protein to sediment at a definite rate (sedimentation velocity).

If the concentration, diffusion constant, and approximate shape of the protein are known, the molecular weight or particle size of the protein or other colloid can be calculated either from sedimentation-equilibrium or sedimentation-velocity data (see Fig. 55). One significant contribution of this method is that it is capable of separating particles of different sizes and weights and thus indicating whether the protein under investigation is mono- or polydisperse. Many proteins which were previously considered to be monodisperse are now known to be mixtures of products

varying widely in particle size. It should be recalled, however, that protein particles of the same size (monodisperse) may differ in amino acid composition, thus making the protein a mixture; on the other hand protein particles of different sizes (polydisperse) may have the same amino acid composition and thus be chemically pure. Analogies exist in organic chemistry; thus leucine admixed with a little isoleucine would be monodisperse, although impure; whereas acetic acid dissolved in benzene would be both monomeric and dimeric acetic acid (polydisperse) and yet be all the same compound.

Molecular weights of proteins have been calculated from diffusion and viscosity data. Both diffusion and viscosity are functions of the size, shape, and degree of hydration of the molecule.

FIG. 55. SEDIMENTATION IN THE ULTRACENTRIFUGE OF A MONODISPERSE SOL (HEMO-CYANIN) AND A POLYDISPERSE SOL (GOLD).

From Svedberg: *Colloid Chemistry*, 2nd ed. Reinhold Publishing Corp., New York, 1928.

Proteins, among other substances, can be oriented in an electric field. If the direction of the field is reversed the molecule will reorient in the opposite direction. As the rate of change of direction of the current is increased (i.e., increasing frequency), more and more of the molecules fail to orient properly and the electrical properties of the solution change. The changes in the dielectric properties of a protein solution are also dependent upon the size, shape, and viscosity of the molecule as well as the alternating frequency. Such data have been used to calculate the molecular weight of some proteins.

The final method mentioned above for the estimation of molecular size is based upon the fact that a single protein crystal, when placed in the beam of an x-ray, will cause the beam to be somewhat deflected. From this, the dimensions for a *unit cell* are obtained and from the density of the protein its mass is computed. The molecular weight is calculated by dividing this mass by that of the hydrogen atom ( $1.66 \times 10^{-24}$ ). The results indicate the molecular weight of the protein or some multiple thereof.

Additional methods for determining molecular weight and shape of

proteins are: molecular shape from flow-birefringence data; molecular weight from light scattering of proteins; and dimensions of proteins from electron micrography.

It should be pointed out that values given in the table of molecular weights below may be multiples or fractions of the true molecular weights of the proteins. These methods probably measure the size of the protein particles with considerable accuracy under the particular experimental conditions, but the results do not necessarily indicate the *true* molecular

\* Many values are averages from the literature.  
† See discussion in text.

weight. The discrepancy between apparent molecular weight and true molecular weight is illustrated in the case of insulin.<sup>2</sup> This highly purified protein was believed to have a molecular weight of from 35,000 to 45,000 by the commonly employed physical methods. Modifications of these procedures suggested at first a molecular weight of 12,000 and then of 6,000. The latter value agrees most closely with the chemical analyses of insulin which indicate one residue of glycine, alanine, and isoleucine per mole of protein.

<sup>2</sup> *Nature*, 170, 518 (1952).

**Nature of Protein Solutions.** Studies of the behavior of the serum globulins led Sørensen, some years ago, to conclude that euglobulin and pseudoglobulin were reversibly combined in a loose chemical combination,  $E_pP_q$ , in which E and P represent euglobulin and pseudoglobulin complexes, respectively, combined in the relative proportions of  $p$  and  $q$ . Subjecting serum to such procedures as dialysis, or fractionation with ammonium sulfate, results in a shifting of the proportions of E and P with the resultant formation of more soluble and less soluble complexes of the two proteins. Sørensen failed, even after repeated fractionations, to prepare samples of either euglobulin or pseudoglobulin that were completely free from the other protein. These results with the globulins led to a series of investigations of other proteins with the result that highly purified preparations of serum albumin, casein, and gliadin were each found to consist of mixtures of an unknown number of proteins of similar character combined in a reversible manner. Such proteins, according to Sørensen, represent "reversibly dissociable component systems" and may be represented by the formula  $A_xB_yC_z \dots$ , in which A, B, C, etc., represent components of a definite character and composition (e.g., polypeptides) while  $x, y, z$ , etc., indicate the number of such components in the more complex system. In each component, the atoms or groups of atoms, such as amino acids, are linked together by means of strong chemical bonds, whereas the complexes are formed by the union of these components through weak, residual valences. Chemical or physical agents that act on the chemical bonds produce irreversible changes in the protein molecule whereas the residual valences respond to changes in salt concentration, pH, or temperature in a reversible manner. Although the various fractions obtained by the fractionation methods employed possess the essential properties of the initial material, they exhibit variations in physical properties and chemical composition that are considered to be due to the varying amounts of the individual components in each fraction. In no case has Sørensen succeeded in isolating a component which could not be further fractionated by appropriate methods.

Applying these conceptions to biological systems, we find that not only may comparatively simple components combine with each other by means of their residual valences to form protein complexes, but these complexes may themselves combine to form still more complicated structures. In serum, for example, we probably have not only such component systems as albumins and globulins, which may be isolated by suitable methods, but also more complex systems in which these proteins are combined in varying proportions not only with each other but with other serum constituents, such as the lipides. In protoplasm, instead of relatively inert, independent substances, there are probably complex systems composed of protein, lipide, and carbohydrate in equilibrium with each other (*orosins*) and constantly shifting in response to changes in environment. The multiplicity and flexibility of such systems may be of profound importance in determining the adaptability of the organism to its environment.

If we accept Sørensen's views on proteins, we can understand the extraordinary difficulties encountered in the isolation of individual proteins

from such complex materials as serum and egg white, and can explain results obtained in Svedberg's laboratory on these substances. Svedberg found, for example, that *there was no substance in fresh egg white with a molecular weight corresponding to that of the crystallized ovalbumin*, but that this substance appeared only after the egg white was treated with ammonium sulfate, as in the crystallization method employed. Similarly, Svedberg found that half-saturation of serum with ammonium sulfate precipitated a globulin fraction which was homogeneous and had a definite molecular weight, and that the euglobulin and pseudoglobulin appeared only after this substance was subjected to further fractionation processes. It thus appears that the proteins with which we are familiar exist in nature only as part of more complex systems, and that even these purified proteins may themselves be complexes formed by the union of several simpler components. The problem of determining the structure and properties of the protein molecule thus depends upon the development of suitable methods for the isolation, in pure form, of the comparatively simple components.

The complexity of the serum proteins is illustrated by the large number of components which one is able to obtain by suitable fractional precipitation of serum. This subject is discussed in detail in Chapter 22.

**Colloidal Behavior of Protein Solutions.** The proteins form colloidal solutions of the type known as emulsoids, or hydrophilic colloids. One of the most characteristic properties of emulsoids, as pointed out in Chapter 1, is that such systems have two stability factors, charge and hydration, either of which is capable of keeping the particle in solution. Individual proteins show marked differences in the hydration of their particles. Most proteins are soluble in dilute acids and alkalies, the particles acquiring positive or negative charges depending upon the pH of the solution. For every protein, there is a definite characteristic pH, known as the *isoelectric point*, at which the particles are electrically neutral and cease to migrate to the poles of an electrical field. Although all proteins are least soluble at their isoelectric points, certain proteins such as gelatin or ovalbumin remain in solution when brought to their respective isoelectric points. On the other hand, less soluble proteins such as casein and edestin remain in solution only at acid or alkaline reaction and precipitate when their solutions are brought to the isoelectric point. Ovalbumin thus behaves as a typical emulsoid, forming stable solutions of neutral particles. Casein acts more like a suspensoid, the particles of which flocculate when their charges are neutralized. The effect of hydration and charge on the colloidal properties and stability of protein solutions is illustrated in Fig. 56, adapted from Kruyt.

The determination of the true nature of protein solutions is complicated by the fact that the proteins are unique colloids, since in addition to their typically colloidal properties they function as amphoteric electrolytes because of the free amino and carboxyl groups which their molecules contain. A great deal of confusion existed as to whether the reactions of proteins with acids and bases are chemical reactions, taking place in stoichiometric proportions, or colloidal reactions following various laws of adsorption. Much of this confusion is probably due to differences in the

nature of the particles present in different protein solutions. The work of Pauli, of Sørensen and of Loeb, and more especially the fine work of Svedberg, discussed above, indicates that in solutions of such proteins as ovalbumin, hemoglobin, and edestin, the material is dispersed in the form of individual molecules of protein and not as molecular aggregates. Such proteins therefore form molecular solutions whose colloidal properties are due entirely to the comparatively large size of the individual molecules. Solutions of other proteins, such as gelatin and casein, probably contain molecular aggregates as well as individual molecules. This point of view is supported by the growing mass of evidence obtained from

FIG. 56. COLLOIDAL BEHAVIOR OF PROTEIN SOLUTIONS.

ultracentrifugal and ultrafiltration experiments as well as from numerous studies on the physicochemical properties of protein solutions.

**Behavior of Proteins as Amphoteric Electrolytes: Isoelectric Points of Proteins.** It is currently believed that proteins behave as molecular solutions of amphoteric electrolytes which exhibit typical colloidal properties because of the large size of the individual molecules. These large molecules contain reactive amino and carboxyl groups which are capable of entering into true chemical combination with acids and bases. In choosing between the chemical and colloidal interpretations of protein reactions, it is well to consider, as pointed out by Svedberg, that colloidal and chemical forces are fundamentally the same, since both are electrical in character and depend upon the attraction and repulsion of negative electrons and positive nuclei. It is quite probable that different proteins vary in their reactions because of the fact that solutions of certain proteins undoubtedly contain individual molecules, but others contain molecular aggregates of various sizes. In the present state of our knowledge of protein chemistry we may assume that the proteins exhibit both chemical and colloidal properties, the former being due to the presence of reactive groups in the protein molecule and the latter being dependent

upon changes in the charge and hydration of the particles in solution, whether molecules or molecular aggregates.

Considered as amphoteric electrolytes, the proteins combine with acids and bases to form salts which ionize into a colloidal protein ion and one or more crystalloidal ions. According to the work of Loeb, Sørensen, Pauli, Michaelis, Cannan, and their co-workers, this combination takes place in definite proportions in accordance with the laws of classical chemistry. A protein at its isoelectric point is either entirely without charge—i.e., completely un-ionized—or else, according to the *zwitterion* hypothesis of Bjerrum, carries equal numbers of positive and negative charges due to complete dissociation of equal numbers of acid and basic groups in the molecule. Isoelectric protein may thus be represented by the formulas:

Here R stands for the nucleus of the protein molecule. The addition of acid to isoelectric protein results in the formation of a protein salt (e.g., protein chloride) which ionizes into a positive protein ion and a negative

acid ion. In the same way the addition of alkali to isoelectric protein results in the formation of a salt which ionizes into a positive metal ion and

a negative protein ion.<sup>3</sup> In solutions acid to their isoelectric points, therefore, the proteins exist as positively charged ions, capable of combining with negative ions to form salts, while in solutions alkaline to their isoelectric points proteins exist as negatively charged ions which can combine only with positive ions. Loeb added solutions of silver nitrate and potassium ferrocyanide to powdered gelatin which had been previously brought to various hydrogen-ion concentrations by soaking in appropriate solutions of acid and alkali. He showed that gelatin combines with silver only when the solutions are on the alkaline side of its isoelectric

<sup>3</sup> The above reactions make use of the older formula for isoelectric protein. The same products are formed according to the zwitterion hypothesis, the only difference being in the mechanism involved. (See section on amino acids, Chapter 4.)

point ( $\text{pH} > 4.7$ ), and with ferrocyanide only on the acid side of its isoelectric point ( $\text{pH} < 4.7$ ). At the isoelectric point gelatin behaves as though it were un-ionized, since it does not combine with either positive ions (cations) or negative ions (anions).

The isoelectric points of the proteins are of especial significance in protein chemistry, because the properties of the proteins undergo unique changes at these points. It has already been pointed out that proteins are ionized and can enter into chemical combination only in solutions which are acid or alkaline with respect to their isoelectric points. The solubility of the proteins, especially those proteins which resemble the suspensoids in their colloidal behavior, is either negligible or at a minimum at the isoelectric points. Other physical properties of the proteins such as viscosity, osmotic pressure, swelling, etc., are also at a minimum at the isoelectric points. According to Loeb these properties are dependent upon a Donnan equilibrium set up between the particles and the surrounding dispersion medium. The isoelectric points of a number of the more common proteins are given in the following table.

ISOELECTRIC POINTS OF SOME COMMON PROTEINS

| <i>Protein</i>              | <i>pH</i> |
|-----------------------------|-----------|
| Ovalbumin.....              | 4.55–4.90 |
| Edestin.....                | 5.5–6.0   |
| Serum albumin.....          | 4.88      |
| Serum globulin (horse)..... | 5.5       |
| Gelatin.....                | 4.80–4.85 |
| Casein.....                 | 4.55      |
| Hemoglobin (reduced).....   | 6.79–6.83 |
| Hemoglobin (oxidized).....  | 6.7       |
| Gliadin.....                | 6.5       |
| Protamines.....             | 12.0–12.4 |
| Silk fibroin.....           | 2.0–2.4   |
| Myosin.....                 | 6.2–6.6   |
| Pepsin.....                 | <1.0      |
| $\beta$ -Lactoglobulin..... | 5.2       |
| Insulin.....                | 5.30–5.35 |

EXPERIMENTS ON PROTEINS

The proteins are characterized by the fact that they contain nitrogen, in addition to carbon, hydrogen, and oxygen; by the colloidal nature of their solutions; and by a series of color and precipitation reactions. In the following sections the technique and interpretation of these reactions will be discussed.

A. COMPOSITION TESTS

Since the proteins always contain nitrogen, a positive test for this element indicates the possibility that the material under examination is a protein. A negative test for nitrogen definitely eliminates the possibility of protein.

1. *General Composition Test.* Heat some powdered egg albumin in a dry test tube in which is suspended a strip of moistened red litmus paper and across the mouth of which is placed a piece of filter paper moistened with lead acetate solution. As the powder is heated it chars, indicating the presence of carbon; the fumes of ammonia are evolved, turning the red litmus paper blue and indicating the presence of nitrogen and hydrogen; the lead acetate paper is blackened, indicating the presence of sulfur; and the deposition of moisture on the side of the tube indicates the presence of hydrogen. (Moisture indicates hydrogen only in case both the powder and the test tube are absolutely dry.)

2. *Test for Organic Nitrogen—Lassaigne Test.* Support a clean, dry test tube in a vertical position by means of a clamp placed near the open end. Drop in a small piece of freshly cut sodium (about a 3-mm. cube) which has been wiped free from oil with a piece of filter paper. Heat the bottom of the tube until a layer of sodium vapor about 1 cm. thick is formed. Drop a small amount of the material to be tested (enough to cover the end of a penknife or small spatula) directly on top of the hot sodium, avoiding contact with the upper wall of the tube. Heat strongly until most of the sodium has vaporized or until thick fumes cease to come off. When cool add a few milliliters of distilled water. Heat the contents to boiling and filter. If the fusion with sodium has been carried out satisfactorily, the filtrate will be colorless. Otherwise it should be rejected and the fusion repeated.

Boil 2 ml. of the clear, colorless filtrate for about a minute with a few drops of 10 per cent sodium hydroxide and 1 or 2 (no more) drops of a freshly prepared, saturated solution of ferrous sulfate. Cool, add dilute HCl, drop by drop, until the solution becomes acid and the precipitate of ferrous hydroxide dissolves. The formation of a precipitate of prussian blue (ferric ferrocyanide) or of a blue or green color in the solution indicates the presence of organic nitrogen in the original material. If the solution remains colorless add a drop or two of ferric chloride solution. If nitrogen is present the solution will turn blue or green and a blue precipitate will usually form on standing.

The fusion of a nitrogen-containing organic compound with sodium results in the formation of sodium cyanide. This, when heated with ferrous sulfate in alkaline solution forms sodium ferrocyanide. The sodium ferrocyanide reacts with the ferric ion usually present, or with the added ferric ion, to form the blue ferric ferrocyanide. An excess of acid is to be avoided since the formation of the ferric ferrocyanide is much more delicate in the presence of only a slight excess of acid. The reactions involved are as follows:

An excess of ferrous sulfate must be avoided since, as these equations show, this would tend to stop the reaction at the  $\text{Fe}(\text{CN})_2$  stage and thus prevent the formation of the characteristic blue ferrocyanide.

3. *Tests for Sulfur.* A. TESTS FOR CYSTINE AND CYSTEINE SULFUR. (1) To equal volumes of KOH and egg albumin solutions in a test tube add 1 to 2 drops of lead acetate solution and boil the mixture. Cystine or cysteine sulfur is indicated by a darkening of the solution, the color deepening into a black if sufficient sulfur is present. Add hydrochloric acid and note the character-

istic odor evolved from the solution. Write the reactions for this test. (2) Place equal volumes of KOH and egg-albumin solutions in a test tube and boil the mixture vigorously. Cool, make acid with glacial acetic acid, and add 1 to 2 drops of lead acetate. A darkening indicates the presence of cysteine or cystine sulfur.

B. TEST FOR TOTAL SULFUR. (*Cystine, Cysteine, and Methionine*). Place the substance to be examined (powdered egg albumin) in a small porcelain crucible, add a suitable amount of solid fusion mixture (sodium carbonate and potassium nitrate mixed in the proportion 2:1), and heat carefully until a colorless mixture results. (Sodium peroxide may be used in place of this fusion mixture if desired.) Cool, dissolve the cake in a little warm water, and filter. Acidify the filtrate with hydrochloric acid, heat it to the boiling point, and add a small amount of barium chloride solution. A white precipitate forms if sulfur is present. What is this precipitate?

As mentioned in the preceding chapter, sulfur is present in proteins as cystine, cysteine, or methionine. Cystine and cysteine sulfur was formerly termed *unoxidized, loosely combined, mercaptan, or lead-blackening sulfur*. Methionine sulfur because of its greater stability toward alkaline lead acetate was called *oxidized or acid sulfur*. These terms are generally misleading and, in the case of the term *oxidized*, incorrect. The majority of proteins contain more methionine S than cystine + cysteine S. Exceptions are keratins, insulin, and certain serum albumins which contain all or almost all their sulfur in the form of cystine and cysteine. Silk fibroin and many protamines are devoid of sulfur.

## B. COLOR REACTIONS OF PROTEINS

These color reactions are due to a reaction between some one or more of the constituent radicals or groups of the complex protein molecule and the chemical reagent or reagents used in any given test. Not all proteins contain the same amino acids and for this reason the various color tests will yield reactions varying in intensity of color according to the nature and amount of the groups contained in the particular protein under examination. Various substances not proteins respond to certain of these color reactions, and it is therefore essential to submit the material under examination to several tests before concluding definitely regarding its nature.

**1. Millon's Reaction.** To 5 ml. of a dilute solution of egg albumin<sup>4</sup> in a test tube, add 3 to 4 drops of Millon's reagent.<sup>5</sup> Mix and bring the mixture gradually to the boiling point by heating over a small flame. Proteins like egg albumin, which are precipitated by strong mineral acids, yield a white precipitate which gradually turns red upon heating; whereas other proteins, like the secondary proteoses and peptones, yield only a red solution under the same conditions. If no color develops, add 2 to 3 more drops of the reagent

<sup>4</sup> This egg albumin solution may be prepared by beating egg white with 6 to 10 volumes of water. The material is strained through cheesecloth to remove the precipitate of ovomucin formed, and then filtered through filter paper and the filtrate used in the tests. A 1 per cent solution may also be prepared from powdered or scale egg albumin by soaking the material in a small quantity of water (sufficient to moisten it thoroughly) for several hours, then diluting to volume, stirring until dissolved, and filtering.

<sup>5</sup> See Appendix.

and heat again. An excess of the reagent is however to be avoided since it may produce a yellow color which is not a positive reaction. Repeat the test, using a 0.1 per cent solution of phenol instead of the protein, and note the red color produced upon heating.

This test is a particularly satisfactory one for use on solid proteins. In this case, dilute some of the reagent with 3 to 4 volumes of distilled water, add the solid, and heat gently as above. The particles of undissolved protein will gradually turn red; if any of the protein dissolves, the solution will also assume a red color.

The reaction is due to the presence of the hydroxyphenyl group,  $-\text{C}_6\text{H}_4\text{OH}$ , in the protein molecule; and any phenolic compound which is unsubstituted in the 3,5 positions such as tyrosine, phenol (carbolic acid), and thymol will give the reaction. Inasmuch as the tyrosine or halogenated tyrosine grouping is the only hydroxyphenyl grouping which definitely has been proved to be present in the protein molecule, it is evident that proteins respond to Millon's reaction because of the presence of this amino acid. The test is not a very satisfactory one for use in solutions containing inorganic salts in large amount, since the mercury of the Millon's reagent is thus precipitated and the reagent rendered inert. This reagent is therefore never used for the detection of protein material in the urine. If the solution under examination is strongly alkaline it should be neutralized, inasmuch as the alkali will precipitate yellow or black oxides of mercury.

**2. Millon-Nasse Reaction.** This is an adaptation of the Millon test and can be used in the presence of considerable quantities of inorganic salts, especially NaCl.

To 5 ml. of a dilute solution of protein in a test tube, add 1 ml. of a 15 per cent solution of mercuric sulfate in 6 N sulfuric acid. Place the tube in a boiling water bath for 10 minutes, cool the contents in water for 5 to 10 minutes, and add 1 ml. of 1 per cent  $\text{NaNO}_2$ . A deep-red color indicates tyrosine or other 3,5 unsubstituted phenol.

**3. Xanthoproteic Reaction.** To 2 to 3 ml. of egg-albumin solution in a test tube add 1 ml. of concentrated nitric acid. A white precipitate forms, and upon heating turns yellow and finally dissolves, imparting to the solution a yellow color. Cool the solution and carefully add ammonium hydroxide or sodium hydroxide in excess. Note that the yellow color deepens into an orange. Repeat the test using a 0.1 per cent phenol solution instead of the protein, and note the production of the yellow and, later, the orange color.

This reaction is due to the presence in the protein molecule of the phenyl group,  $-\text{C}_6\text{H}_5$ , with which the nitric acid forms certain nitro modifications. The particular complexes of the protein molecule which are of especial importance in this connection are those of tyrosine and tryptophan. Phenylalanine does not respond to this test as it is ordinarily performed. The test is not a satisfactory one for use in urinary examination because of the color of the end reaction.

**4. Glyoxylic Acid Reaction (Hopkins-Cole).** Place 2 to 3 ml. of egg albumin solution and an equal volume of glyoxylic acid ( $\text{CHO}\cdot\text{COOH} + \text{H}_2\text{O}$  or  $\text{CH}(\text{OH})_2\text{COOH}$ ) solution (Hopkins-Cole reagent)<sup>6</sup> in a test tube and mix thoroughly. Incline the tube and permit 5 to 6 ml. of concentrated sulfuric acid to flow slowly down the side of the tube, thus forming a sharp layer of acid

<sup>6</sup> See Appendix.

beneath the protein mixture. When stratified in this manner a reddish-violet color forms at the zone of contact of the two fluids. If the color does not appear after standing for a few minutes, the tube may be rocked gently to cause a slight mixing of the liquids at the interface. If the two liquids are mixed by gentle stirring the precipitate of protein dissolves and the violet color spreads throughout the solution.

This color is due to the presence of the *tryptophan group* (see p. 142). Gelatin does not respond to this test. Nitrates ( $\text{NaNO}_3$  and  $\text{KNO}_3$ ), chlorates, nitrites, or excess of chlorides prevent the reaction, but a trace of copper sulfate will increase its sensitivity. The sulfuric acid used must be pure.

**5. Biuret Test.** To 2 to 3 ml. of egg-albumin solution in a test tube add an equal volume of 10 per cent sodium hydroxide solution, mix thoroughly, and add a 0.5 per cent copper sulfate solution drop by drop, mixing between drops, until a purplish-violet or pinkish-violet color is produced. (If too much copper sulfate is added the violet color may be obscured by the blue precipitate of copper hydroxide formed.) The color depends upon the nature of the protein: proteoses and peptones give a decided pink; the color produced with gelatin is not far removed from a blue.

Repeat the biuret test on some biuret, formed from urea as follows: Place about one-eighth inch of urea in a clean dry test tube and heat gently over a small flame. The urea melts and then effervesces, and the biuret formed appears as a white solid in the bottom of the tube. Note the odor of the gas given off during the heating. Allow the tube to cool, dissolve the biuret in 3 to 4 ml. of 10 per cent sodium hydroxide, and add 0.5 per cent copper sulfate solution, drop by drop, until the pink color appears.

The biuret test may also be carried out with a stable biuret reagent, prepared by adding 1 per cent copper sulfate solution, drop by drop, with constant stirring, to some 40 per cent sodium hydroxide solution until the mixture assumes a deep blue color. This reagent may be used in either of two ways. It may be added directly to the protein solution, a drop at a time, with mixing, until the solution assumes a violet color; or two or three drops of the reagent may be permitted to flow down the side of the inclined tube. In this case the reagent forms a layer beneath the protein solution and the violet color appears at the interface between the two liquids.

The biuret test is given by those substances whose molecules contain two carbamyl ( $-\text{CONH}_2$ ) groups joined either directly together or through a single atom of nitrogen or carbon. Similar substances which contain (in place of the  $-\text{CONH}_2$  group)  $-\text{CSNH}_2$ ,  $-\text{C}(\text{NH})\text{NH}_2$ , or  $-\text{CH}_2\text{NH}_2$  also respond to the test. It follows from this fact that substances which are nonprotein in character but which contain the necessary groups will respond to the biuret test. As examples of such substances the following may be cited:

Oxamide

The test derives its name from the fact that biuret, which is formed on heating urea to  $180^\circ \text{C.}$ , responds to the test. Proteins respond positively since there are pairs of  $\text{CONH}$  groups in the molecule.

According to Schiff the end reaction of the biuret test is dependent upon the formation of a copper-potassium-biuret compound (cupripotassium biuret or biuret potassium cupric hydroxide). This substance was obtained by Schiff in the form of long red needles and has been formulated as follows:

Haurowitz<sup>7</sup> assumes that a copper coordination complex with the following ring structure is probably produced:

If much magnesium sulfate is present a precipitate of magnesium hydroxide forms which interferes with the test. If much ammonium sulfate is present a large excess of alkali must be used.

**6. The Triketohydrindene Hydrate (Ninhydrin) Reaction.** To 5 ml. of dilute protein solution, which must be approximately between pH 5 and pH 7,<sup>8</sup> add 0.5 ml. of a 0.1 per cent solution of triketohydrindene hydrate, heat to boiling for one to two minutes, and allow to cool. A blue color develops if the test is positive.

This test gives positive results with proteins, peptones, peptides, amino acids, and other primary amines, including ammonia. For further discussion see p. 129.

### C. PRECIPITATION REACTIONS OF PROTEINS

The proteins are precipitated from solution by salts of the heavy metals (e.g.,  $\text{HgCl}_2$ ,  $\text{AgNO}_3$ ,  $\text{CuSO}_4$ ,  $\text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_2$ , etc.); by certain acids some of which are called *alkaloidal reagents* (picric acid, phosphotungstic acid, tannic acid, metaphosphoric acid, etc.); by concentrated solutions of such salts as ammonium sulfate, sodium sulfate, and sodium chloride; and by ethyl and methyl alcohol. Although these reactions have been used for many years for the separation and characterization of proteins, there is still no definite evidence concerning the nature of the mechanisms

<sup>7</sup> Haurowitz: *Chemistry and Biology of Proteins*, New York, Academic Press, Inc., 1950, p. 11.

<sup>8</sup> A few drops of pyridine or a few crystals of sodium acetate may be used to adjust the pH.

involved. Some of this uncertainty is due to the experimental difficulties involved in the isolation of the pure products formed in these reactions. There is also a great deal of confusion due to attempts by various authors to interpret these reactions exclusively on either a chemical or a colloidal basis.

In the case of the acids, the evidence suggests that the protein combines with the acid radical to form insoluble salts, such as protein tannate, protein phosphotungstate, etc. This is in agreement with the views of Loeb, who pointed out that proteins combine with negative, or acid, ions only on the acid side of their isoelectric points. In agreement also is the fact that if, instead of the free acids, the salts of these acids are added to neutral solutions of protein, no precipitates result until the solution is acidified. Some of the reactions obtained with the salts of the heavy metals are probably similar in character; precipitates of silver proteinate, for example, are formed on the alkaline side of the isoelectric points. The reactions are, however, complicated by the fact that in some cases the first addition of salt causes the formation of a precipitate which dissolves in excess of salt and then reprecipitates when more salt is added. The difficulties involved in arriving at a rational explanation of these reactions are intensified by the fact that individual proteins show great differences in behavior, probably because of differences in the hydration and dispersion of the particles in solution, denaturation, etc. In general, precipitants of this class usually cause extensive intramolecular changes in the protein molecule.

The proteins, in common with other emulsoids, are precipitated by concentrated solutions of such salts as ammonium sulfate, sodium sulfate, sodium chloride, etc. In these cases, as discussed in Chapter 1, precipitation is apparently due to the neutralization and dehydration of the molecules and molecular aggregates in solution. The protein precipitated by these salting-out methods is unaltered (native) and usually redissolves when treated with fresh portions of the original solvent. The concentration of salt required for the precipitation of a protein depends on the particular protein and on the pH of the solution—i.e., on the charge on the protein complex. These variations will be considered in the next chapter in connection with the properties of the various classes of proteins.

The proteins are also precipitated by dehydrating agents, such as alcohols and acetone. The addition of alcohol to electrolyte-free solutions of proteins converts them into suspensoids, which flocculate upon the addition of a few drops of salt solution. Precipitation by alcohol is most effective at the isoelectric point of the protein. Besides precipitating proteins, alcohol acts on certain proteins, such as egg albumin, to produce intramolecular changes which affect the solubility and other properties of the protein. This phenomenon, known as denaturation, will be discussed more fully in the next section. The denaturing effect of alcohol on some proteins may be minimized by the use of temperatures around 0° C. or below. Prolonged contact with alcohol (or any other denaturing agent, for that matter) produces an irreversible coagulation of the protein. The fixing of tissues for histological examination is an example of the coagulating action of alcohol on proteins.

Colloidal iron, kaolin, and alumina cream are frequently used for removing proteins from solution. These substances probably act by adsorption and their use has been adapted to various quantitative methods.

**1. Effect of Strong Acid and Alkali.** Place a few ml. of concentrated nitric acid in a test tube, incline the tube, and add dilute egg albumin slowly from a pipet, allowing the solution to run down the side of the tube and form a layer over the nitric acid. Note the appearance of a protein precipitate at the zone of contact between the two fluids. Now mix the contents of the tube thoroughly by careful shaking. Is protein precipitated by concentrated nitric acid?

Repeat the above experiment using concentrated sulfuric acid, concentrated hydrochloric acid, acetic acid, and concentrated sodium hydroxide. How do these various reagents differ in their action on proteins? Allow the tubes to stand overnight or longer and note any further changes.

The formation of a protein precipitate by layering the solution over nitric acid as described above is frequently used as a test for protein in urine and other fluids (Heller's test, see p. 830).

**2. Precipitation by Metallic Salts.** Prepare six tubes each containing 2 to 3 ml. of dilute egg-albumin solution. To the first add mercuric chloride solution, drop by drop slowly, until an excess of the reagent has been added, and note any changes which may occur. Unless the reagent is added very gradually the formation of the precipitate may not be noted, due to its solubility in excess of the reagent. Repeat the experiment with lead acetate, silver nitrate, copper sulfate, ferric chloride, and barium chloride, using very dilute solutions.

Egg albumin is used as an antidote for lead or mercury poisoning. Why? Is it an equally good antidote for the other metallic salts tested?

**3. Precipitation by Alkaloidal Reagents.** Prepare six tubes, each containing 2 to 3 ml. of dilute egg-albumin solution. To the first add picric acid, drop by drop, until an excess of the reagent has been added, noting any changes which may occur. Repeat the experiment with trichloroacetic acid, tannic acid, phosphotungstic acid, phosphomolybdic acid, and potassium mercuric iodide. Are these precipitates soluble in excess of the reagent? Acidify with hydrochloric acid before testing with the last three reagents.

**4. Precipitation by Ferrocyanide.** To 5 ml. of dilute egg-albumin solution in a test tube add 5 to 10 drops of acetic acid. Mix well and add potassium ferrocyanide, drop by drop, until a precipitate forms. This reaction is very sensitive.

**5. Fractional Precipitation of Proteins by Concentrated Salt Solution.** (a) Obtain some dilute egg-white solution which has been prepared by thoroughly mixing one volume of raw egg white with four volumes of 1 per cent sodium chloride solution and filtering. To a portion of the dilute egg-white solution add an equal volume of a saturated solution of ammonium sulfate and mix. Does egg white contain a protein which is precipitated by half-saturated ammonium sulfate solution? Dilute a portion of the mixture with some distilled water. Is the precipitation reversible? To the remainder of the mixture add an excess of solid ammonium sulfate and stir until the

solution is saturated with the salt. What happens? Again dilute a portion of the mixture with water. Is this precipitation reversible? Filter the remainder of the mixture and test a portion of the precipitate by the Millon test. Test the filtrate by the biuret test, using a saturated solution of ammonium sulfate as a control and adding the same amounts of alkali and copper sulfate solution to both control and filtrate. What are your conclusions?

(b) Repeat the above experiment, using sodium chloride instead of ammonium sulfate. How do the results differ from those obtained with ammonium sulfate? At the saturation point with sodium chloride, add 2 to 3 drops of acetic acid. What occurs?

All proteins except peptones are precipitated by saturating their solutions with ammonium sulfate. Most globulins are precipitated by half-saturation with ammonium sulfate or full saturation with sodium chloride. If the saturated sodium chloride solution is subsequently acidified, all proteins except peptones are precipitated.

Soaps may be salted out in a similar manner (see p. 108).

**6. Precipitation by Alcohol.** (a) INFLUENCE OF ELECTROLYTES. Prepare an electrolyte-free solution of egg albumin as follows: Place the albumin solution in a dialyzing bag (see p. 10), add a drop of toluene as a preservative, and tie the mouth of the bag securely. Immerse in a large beaker of distilled water and allow to stand for several days, changing the water at intervals. Remove the albumin solution from the bag and filter. Test the filtrate for chloride. It should be negative; if not, the dialysis must be repeated.

Place a 5-ml. portion of the salt-free albumin solution in each of two test tubes and add 10 ml. of 95 per cent alcohol to each tube. Mix. Now to one tube add a pinch or two of solid sodium chloride and again mix. Compare results in the two tubes. What is the effect of alcohol on protein in the absence of electrolytes? What is the effect of added electrolyte? Explain. Dilute some of the suspension with water. Does the precipitated protein redissolve?

(b) INFLUENCE OF ISOELECTRIC POINT. See Exp. 2, below.

D. ISOELECTRIC POINTS OF PROTEINS

**1. Isoelectric Point and Solubility of Casein.** Into a 50-ml. volumetric flask introduce 0.25 g. of pure casein. Add about 20 ml. of water and exactly 5 ml. of N NaOH. When solution is complete add exactly 5 ml. of N acetic acid and dilute to 50 ml. Mix well. This is a solution of casein in 0.1 N sodium acetate. Set up a series of nine tubes as follows:

| Tube No.....                | 1    | 2    | 3    | 4   | 5  | 6  | 7  | 8  | 9   |
|-----------------------------|------|------|------|-----|----|----|----|----|-----|
| Distilled water ml. ....    | 8.38 | 7.75 | 8.75 | 8.5 | 8  | 7  | 5  | 1  | 7.4 |
| 0.01 N acetic acid ml. .... | 0.62 | 1.25 | ..   | ..  | .. | .. | .. | .. | ..  |
| 0.1 N acetic acid ml. ....  | ..   | ..   | 0.25 | 0.5 | 1  | 2  | 4  | 8  | ..  |
| 1.0 N acetic acid ml. ....  | ..   | ..   | ..   | ..  | .. | .. | .. | .. | 1.6 |

To each tube add 1 ml. of the casein-sodium acetate solution, blowing it in from a pipet and shaking the tubes immediately. Note the turbidities just after mixing and after 10 and 30 minutes. Record the results as below,

indicating no turbidity by 0, degrees of turbidity by + signs, and degrees of precipitation by X.

| <i>Tube No</i> .....          | 1   | 2   | 3   | 4   | 5   | 6   | 7   | 8   | 9   |
|-------------------------------|-----|-----|-----|-----|-----|-----|-----|-----|-----|
| pH.....                       | 5.9 | 5.6 | 5.3 | 5.0 | 4.7 | 4.4 | 4.1 | 3.8 | 3.5 |
| Turbidity, immediate.....     | 0   | 0   | +   | ++  | +++ | ++  | +   | +   | 0   |
| Turbidity after 5 minutes.... | 0   | 0   | +   | +++ | XXX | XX  | ++  | +   | 0   |

The precipitation should be greatest in Tube 5 which has a pH of 4.7, near the isoelectric point and point of least solubility of casein. The acidity in each tube may be actually determined by the electrometric method or may be calculated from the concentrations of sodium acetate and acetic acid by means of the Henderson-Hasselbalch equation (see p. 33).

2. *Isoelectric Point and Precipitation of Gelatin by Alcohol.* Gelatin and many other proteins are quite soluble in water even at their isoelectric points. They do, however, precipitate more readily at this point if some precipitating agent such as alcohol is added.

Prepare a series of test tubes as follows:

| <i>Tube No</i> .....         | 1    | 2    | 3   | 4  | 5  | 6  | 7   | 8   | 9   |
|------------------------------|------|------|-----|----|----|----|-----|-----|-----|
| 0.1 N sodium acetate ml..... | 2.00 | 2.00 | 2.0 | 2  | 2  | 2  | 2.0 | 2.0 | 2.0 |
| 0.1 N acetic acid ml.....    | 0.12 | 0.25 | 0.5 | 1  | 2  | 4  | ..  | ..  | ..  |
| 1.0 N acetic acid ml.....    | ..   | ..   | ..  | .. | .. | .. | 0.8 | 1.6 | 3.2 |
| Distilled water ml.....      | 3.88 | 3.75 | 3.5 | 3  | 2  | 0  | 3.2 | 2.4 | 0.8 |
| 1% gelatin ml.....           | 2.00 | 2.00 | 2.0 | 2  | 2  | 2  | 2.0 | 2.0 | 2.0 |

Mix the contents of the tubes well and add 95 per cent alcohol to Tube 5 until a very faint cloudiness is produced (ordinarily about 8 ml. are required). Add the same amount of alcohol to each of the other tubes. Examine after 30 minutes. The results usually obtained, with approximate pH for each tube, are as follows:

| <i>Tube No</i> ..... | 1   | 2   | 3   | 4   | 5   | 6   | 7   | 8   | 9   |
|----------------------|-----|-----|-----|-----|-----|-----|-----|-----|-----|
| Turbidity.....       | —   | —   | —   | ++  | +++ | ±   | —   | —   | —   |
| pH.....              | 6.0 | 5.6 | 5.3 | 5.0 | 4.7 | 4.4 | 4.1 | 3.8 | 3.5 |

The isoelectric point for gelatin is about pH 4.7.

3. *Influence of Acid on Swelling of Gelatin.* Proteins are least hydrated at their isoelectric points. The addition of acid, such as HCl, to gelatin causes it to swell, the process being one of increased hydration. Ions have a strong affinity for water and the addition of acid increases the ionization of the gelatin. In the case of HCl the H ion tends to increase the swelling and the Cl ion to depress it. In high concentrations the latter effect overcomes the former and decreased swelling results. The same result follows the addition of Cl ion as NaCl, which hence tends to decrease swelling. The influence of ions and other substances on the hydration of cell proteins is believed to be

of great biological importance. Relatively slight changes in pH greatly influence protein swelling.

Prepare a series of test tubes as follows:

| <i>Tube No.</i> .....  | 1  | 2  | 3  | 4  | 5  | 6  | 7    | 8     | 9     | 10    |
|------------------------|----|----|----|----|----|----|------|-------|-------|-------|
| 1.0 N HCl ml.....      | 16 | 8  | 4  | .. | .. | .. | ..   | ..    | ..    | ..    |
| 0.1 N HCl ml.....      | .. | .. | .. | 20 | 10 | 5  | 2.5  | 1.25  | 0.62  | 0.31  |
| Distilled water ml.... | 4  | 12 | 16 | 0  | 10 | 15 | 17.5 | 18.75 | 19.38 | 19.69 |

Cut strips as nearly the same size as possible (5 cm. × 0.5 cm.) from a sheet of gelatin at least 1 mm. thick. Put a strip in each tube. After 24 hours measure the length of the strips. Results similar to the following may be obtained.

| <i>Tube No.</i> ..... | 1   | 2   | 3   | 4   | 5   | 6   | 7   | 8   | 9   | 10  |
|-----------------------|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|
| Length (cm.).....     | 6.4 | 6.6 | 6.7 | 7.4 | 8.3 | 8.3 | 7.6 | 7.0 | 6.1 | 5.3 |

The greatest degree of swelling will usually be found in tubes containing from 0.025 to 0.05 N HCl corresponding to pH values of 1.3 to 1.6. The reaction within the gelatin particles themselves at the point of maximum swelling is, however, about pH 3.2. This difference in reaction within and without the gel is a consequence of the Donnan equilibrium (see p. 12) which must be considered in all such cases involving the relations of protein ions to other ions in solution. Instead of gelatin strips, 1-g. portions of powdered gelatin (between 30 and 50 mesh) may be placed in 100-ml. graduated cylinders containing suitable solutions and the relative degree of swelling measured. The actual pH of the gel in any case may be determined electrometrically.

4. *Influence of Acidity on Solidification of Gelatin.* The isoelectric point for gelatin (pH 4.7) is the point of minimum viscosity of its solutions and the point at which the gelatin most readily solidifies. This is because at this point the gelatin is least soluble in the more liquid (water) phase and hence imparts less viscosity to it. For the same reason there is a greater tendency for the more solid phase (gelatin) to form the supporting network believed to be the basis of a jelly. Viscosity determinations must of course be made on the liquefied gelatin solution.

Prepare a series of test tubes as follows:

| <i>Tube No.</i> .....          | 1    | 2    | 3    | 4   | 5   | 6   | 7   |
|--------------------------------|------|------|------|-----|-----|-----|-----|
| 0.1 N sodium acetate ml.....   | 1.00 | 1.00 | 1.00 | 1.0 | 1.0 | 1.0 | 1.0 |
| 0.1 N acetic acid ml.....      | 0    | 0.06 | 0.25 | 1.0 | 4.0 | ..  | ..  |
| 1.0 N acetic acid ml.....      | ..   | ..   | ..   | ..  | ..  | 1.6 | 6.4 |
| 1.0 N sodium hydroxide ml..... | 0.05 | ..   | ..   | ..  | ..  | ..  | ..  |
| Water ml.....                  | 6.95 | 6.94 | 6.75 | 6.0 | 3.0 | 5.4 | 0.6 |
| pH (approx.).....              | 8.00 | 5.60 | 5.00 | 4.6 | 4.0 | 3.4 | 2.8 |

To each tube add 3 ml. of a warm 10 per cent solution of gelatin and mix. Place all the tubes in water at 50° C. for a few minutes, then transfer to a large beaker of water at room temperature, noting the time at this point. After a

few minutes in the beaker, the tubes may be removed and placed in a rack to facilitate observation. Note the time required for solidification of the gelatin in each tube. Degree of solidification may be established by tilting the tube and observing whether or not the fluid will flow. Results similar to the following should be obtained.

| Tube No.....                               | 1  | 2  | 3  | 4  | 5  | 6  | 7         |
|--------------------------------------------|----|----|----|----|----|----|-----------|
| Time required for solidification (min.)... | 19 | 17 | 16 | 14 | 19 | 25 | very long |

Observations may be repeated by remelting the jellies. Note also the much greater opacity of the gelatin at the isoelectric point, indicating that most of the gelatin is in the solid phase.

### E. PROTEIN DENATURATION AND ITS REVERSAL

A protein is called a native protein if its amino acid composition and stereochemical structure are unchanged from the natural state. These properties control all the functions of a protein, whether solubility in dilute salt solutions, proteolytic activity, oxygen-carrying capacity, or whatever it may be. These characteristics are altered and the process of denaturation is said to occur when a protein undergoes changes in structure or composition. Chemical and physical agents which cause these changes are called denaturing agents. Their action involves the splitting of some or all of the protein cross linkages with their possible re-formation, in some cases, to cause a rearrangement of the peptide chains.

It is to be expected that proteins will vary widely in their ease of denaturation. Certain proteins, especially those which in solution are fibrous or highly elongated molecules, such as the muscle protein myosin, are easily denatured; others, such as the carbohydrate-rich glycoproteins (ovomucoid, for example) seem to be quite resistant to the usual physical agents causing denaturation.

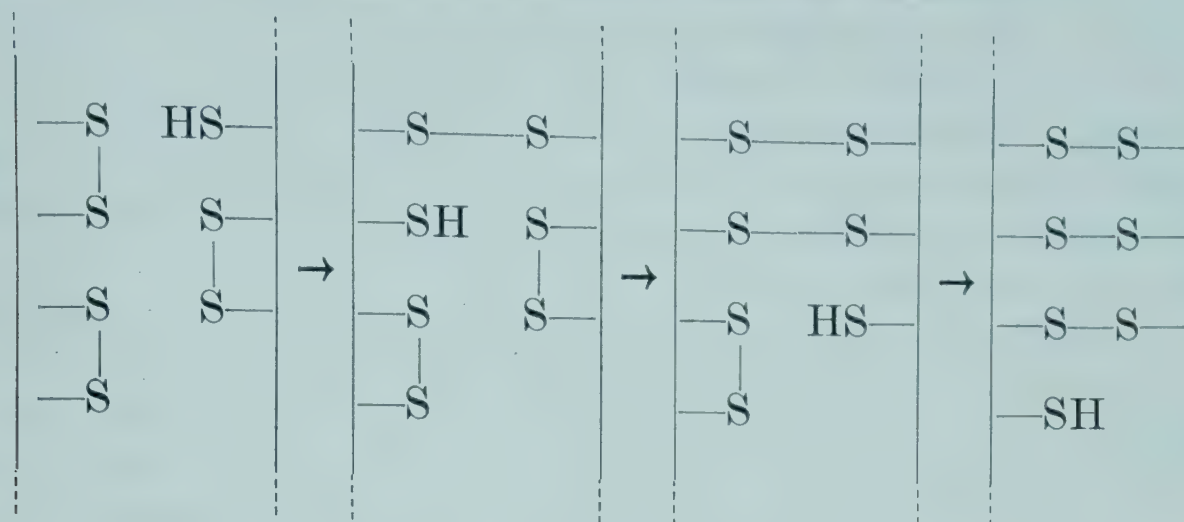

Denaturation may be caused by: (1) heat, which causes splitting of the salt bridges by thermal agitation; (2) mineral acids and alkalies, which alter the ionization of carboxyl and amino groups respectively and thus destroy salt bridges; (3) shaking or stirring, which results in the denaturation of the protein spread over the surface of the air bubbles; (4) grinding, which probably causes mechanical deformation of the peptide chains; (5) ultraviolet radiation, which splits the peptide bonds adjacent to the aromatic rings; (6) ultrasonic waves, which destroy the rings of the aromatic amino acids and whose denaturing power depends on their frequency; (7) neutral chemical agents such as urea and certain acid and guanidine derivatives that act as dipoles to cause cleavage of hydrogen bonds and formation of new ones.<sup>9</sup> It has been suggested<sup>10</sup> that the breaking of hydrogen bonds by urea enables the —SH groups to react with intramolecular —S—S— bridges each of which is then converted into

<sup>9</sup> It has been speculated by Pauling that denaturation at times may consist of end to end aggregation of globular protein molecules. *Nature*, **170**, 518 (1952).

<sup>10</sup> Huggins, et al.: *Nature*, **167**, 592 (1951).

an intermolecular link with the liberation of a new  $\text{—SH}$  group. The continuation of this chain process gives rise to an  $\text{—S—S—}$  cross-linked framework of higher molecular weight and decreased solubility at the isoelectric point. This reaction is formulated as follows:

Denaturation, then, appears to be an all-or-none phenomenon; that is, a protein is either denatured or unchanged from its natural state. Denatured proteins may, under certain conditions, be restored to proteins with many of the properties of the original protein. This is known as renaturation. It appears, however, that renaturation seldom results in the complete transformation of the denatured protein to its original state. Thus we may classify proteins into three groups: natural, denatured, and renatured.

If the foregoing rather specific definition of denaturation is used, then as already stated protein denaturation must have an all-or-none character. However, denaturation seldom is completed in one step but consists of a series of chemical and structural deviations from the original native protein. If these changes are not too extensive, many of the properties possessed by the native protein may be restored. Thus pepsin can be denatured and so lose its proteolytic properties if it is warmed to the proper temperature. When the solution is cooled, the proteolytic activity of the protein is restored—i.e., denaturation is reversed and renaturation results. Likewise, the oxygen-carrying capacity of hemoglobin can be destroyed by denaturing with salicylate. On reversal the restored hemoglobin is very similar to the original untreated hemoglobin. Although many of the properties of the native protein can be restored by reversal regeneration, it is still questionable in many instances whether the reversed protein is *identical* with the original native protein. Many regenerated proteins may simulate certain characteristic properties of the native materials from which they were derived, but still remain denatured proteins.

It is thus apparent that the extent of denaturation and its reversal is primarily dependent upon the methods used. Probably the oldest means of denaturing a protein and one which is familiar to all is illustrated by the marked change in consistency of egg white on cooking, a process which results in extensive denaturation of the albumen proteins. What is seen when egg white is cooked is only the end result of denaturation—the matting together of the fibers of denatured protein to form a tightly adhering coagulum. Denaturation involving less deep-seated changes in protein structure requires more refined methods to detect. The studies of

Roche, Neurath, and others have shown that denatured proteins which other investigators believed to have been entirely reversed to the native form were still denatured when more delicate methods of measurement were employed.

In practice, then, denaturation consists of a series of changes in the protein molecule brought about by various chemical and physical agents. These changes often affect the viscosity, particle size, solubility, resistance to proteolytic enzymes, and formation or disappearance of sulfhydryl groups, and may even cause the loss of certain amino acids or peptides of relatively low molecular weight.

Denatured proteins, because of their reduced solubility, usually flocculate at or near the isoelectric point. This flocculation is ordinarily reversible at room temperature. However, if the suspension at the isoelectric point is heated, the floccules form relatively large, tenacious masses of *coagulated protein* which are not easily redissolved by treatment with dilute acids or alkalies. Denaturation is the primary and important change; flocculation and coagulation, which were often confused with denaturation, are simply visible manifestations of the changes in the protein molecule brought about by denaturation.

**1. Denaturation, Flocculation, and Coagulation of Egg Albumin.** Place 9 ml. of a clear, salt-free solution of egg albumin into each of three test tubes. To the first add 1 ml. of 0.1 N HCl, to the second 1 ml. of a mixture of sodium acetate and acetic acid (pH 4.7), and to the third 1 ml. of 0.1 N NaOH. Heat all three tubes in a boiling water bath for 15 minutes. Cool and examine. To tubes 1 and 3 add 10 ml. of acetate buffer solution, pH 4.7. What happens? Filter off the precipitates in each tube and wash them on the filter papers with distilled water. Precipitates 1 and 3 are denatured egg albumin. Precipitate 2 is coagulated egg albumin.

Suspend each of the precipitates in about 10 ml. of distilled water and divide each suspension into three parts. To the first part add dilute HCl, drop by drop. Does the precipitate dissolve? Repeat with another part of the suspension, adding dilute NaOH. Heat the third parts of suspensions 1 and 3 in a boiling water bath for 15 minutes. Cool and test the solubility of the material in dilute acid and alkali. Does the material now dissolve?

The precipitates of denatured protein, formed by bringing their solutions to the isoelectric point, dissolve readily in a few drops of dilute acid or alkali. The coagulated protein remains insoluble under similar conditions. Heating the precipitate of denatured protein converts it into a coagulated protein, in which case it exhibits the properties characteristic of that type of substance.

## F. IMMUNOLOGICAL REACTIONS OF PROTEINS

Certain materials, when injected into a living animal under proper conditions, stimulate the animal to produce substances which have the power to react with the specific material injected. The substance injected is referred to as the *antigen*, while the specific substances appearing in the blood of the immunized animal are known as *antibodies*. In order to act as antigens the substances must be protein (or combinable with protein) or polysaccharide in nature, colloidal, and foreign to the blood stream of the animal injected. The antibodies are structurally (and possibly chem-

ically) modified serum proteins, usually globulins, induced by the presence of the antigen in those organs in which the formation of serum proteins occurs. Their presence in the blood stream of the immunized animal is recognized by their action on antigens. The type of reaction which takes place between the antigen and antibody depends upon the nature of the antigen. If, for example, the antigen consists of a suspension of red blood corpuscles, the blood serum of the immunized animal, known as the antiserum, acquires the property of hemolyzing this particular type of corpuscle. If the antigen is a suspension of bacteria or other cells, the antiserum will cause these particular cells to clump together or agglutinate.

If the antigen is a soluble protein the antiserum is capable of forming a precipitate with this specific protein, when mixed under proper conditions. This reaction, known as the precipitin reaction, is remarkably delicate and specific. By means of the precipitin reaction it is possible, for example, to detect a specific protein in solutions containing as little as one part in ten million, or even in one hundred million. Furthermore, this reaction is so specific that the antiserum prepared by injecting a solution of hen's egg albumin will precipitate hen's egg albumin but will give no reactions at extreme dilutions with egg albumins from other sources, or with any of the other proteins in egg white. The precipitin reaction is thus of great value in determining the identity and individuality of protein preparations. It permits us to detect differences between similar proteins from closely related sources which, in their chemical composition and properties, are practically indistinguishable. By means of this reaction it may be shown that certain proteins, such as the protein of crystalline lens, are immunologically the same in animals of widely differing species. It has been used to study relationships between various species of plants and of animals. Practically, it is used in medicolegal work to distinguish specifically between human and other bloodstains.

The technique involved in immunization and in carrying out precipitin reactions is illustrated in an experiment on p. 485.

# Proteins: Their Classification and Properties

The classification of the proteins is a very difficult problem because, as was outlined in Chapter 5, they are found in nature not as distinct chemical individuals but as parts of larger complexes formed by the union of various proteins with each other and with carbohydrates and lipides. The problem is further complicated by the fact that individual purified proteins may themselves be separated into components showing individual differences in composition and properties. Until these components are isolated in pure form and their exact structure determined, a classification of proteins based on molecular structure is impossible. The classification offered below is based upon the fact that under specified experimental conditions the proteins in biological materials (e.g., egg white or blood plasma) may be separated into groups which exhibit certain characteristic properties. It should be kept in mind, however, that these proteins probably do not exist as such in the native material, and that, furthermore, their composition and properties are dependent upon the methods used in their isolation. In spite of all its shortcomings such a classification permits the grouping together of proteins with similar properties into fairly definite classes, and must suffice until the information required for a more rigid classification is obtained.

## CLASSIFICATION

### I. SIMPLE PROTEINS

The simple proteins are proteins which may be isolated from biological materials by suitable methods. Although they are usually described as yielding only  $\alpha$ -amino acids or their derivatives on hydrolysis, some members of this class (e.g., ovalbumin, serum albumin, serum globulin) also yield carbohydrates (see p. 119). Many proteins, such as egg albumin, pepsin, trypsin, insulin, hemoglobin, serum albumin, edestin, excelsin, viruses, and Bence-Jones and other urinary proteins, may be obtained in crystalline form. By repeated crystallizations these proteins may thus be separated from other proteins present in the original materials. The simple proteins are further classified into albumins, globulins, glutelins, prolamins, albuminoids, histones, globins, and protamines on the basis of solubility and other characteristic properties, as follows.<sup>1</sup>

---

<sup>1</sup> The subclasses defined are exemplified by proteins obtained from both plants and animals. Appropriate prefixes indicate the origin of the compounds, e.g., ovoglobulin, lactalbumin, etc.

**Albumins** are soluble in salt-free water and coagulable by heat, e.g., ovalbumin from egg white, serum albumin from blood serum, lactalbumins from milk, vegetable albumins.

It is now recognized that serum albumin is not a homogeneous material but can be fractionated by salting-out procedures (*cf.* pp. 163–164) into a number of distinct components all of which have albumin characteristics. The term *serum albumins* is preferable to the more widely used *serum albumin*. These proteins are, however, either not separated or but poorly separated by the widely used ultracentrifuge or electrophoretic methods. (See p. 461.)

**Globulins** are insoluble in salt-free water but soluble in neutral solutions of salts of strong bases with strong acids, such as NaCl, and are coagulable by heat; e.g., serum globulin, lactoglobulin, thyroglobulin, edestin from hemp seed, amandin from almond, and other vegetable globulins.

Serum globulin has been fractionated into several components by ultracentrifuge and electrophoretic methods (see Chapter 22). The three groups most easily identified are called  $\alpha$ ,  $\beta$ , and  $\gamma$  globulins. The  $\gamma$ -globulin fraction of human plasma is the source of almost all the immunologically active proteins of the blood. In fact, it appears that 50 per cent or more of the  $\gamma$ -globulin fraction prepared from pooled human plasma is composed of immunologically active material. During convalescence from illness, there is an increase in immune proteins in the plasma. This increase is accompanied by and accounted for by the increase in  $\gamma$ -globulin. Figure 57 shows a paper electrophoretic pattern of normal human serum.

**Glutelins** are simple proteins insoluble in all neutral solvents, but readily soluble in very dilute acids and alkalies; e.g., glutenin from wheat. These may be mixtures of denatured proteins.

**Prolamins** are simple proteins soluble in 70 to 80 per cent alcohol and insoluble in water, absolute alcohol, and other neutral solvents; e.g., zein from corn, gliadin from wheat and rye, hordein from barley, and bynin from malt. Rice, kafir, and sorghum have also been shown to contain alcohol-soluble proteins. The name prolamins was suggested for these alcohol-soluble vegetable proteins by Osborne, since upon hydrolysis they yield large amounts of proline and ammonia.

**Albuminoids (Scleroproteins)** comprise all fibrous proteins which have a supporting or protective function in the animal organism. In the plant kingdom the albuminoids are probably replaced by cellulose and similar substances.

1. **COLLAGENS**, the principal supporting proteins of skin, tendons, and bones, are resistant to peptic and tryptic digestion. They are converted into the easily digested soluble proteins, the gelatins, by boiling with water, dilute acids, or alkalies and contain large amounts of hydroxyproline.

2. **ELASTINS**, present in elastic tissues (tendons, arteries), are more readily digested by trypsin than by pepsin, are not convertible into gelatin, and give a negative or very weak test for hydroxyproline. Elastic tissue is a mixture of elastin, collagen, and a carbohydrate-containing protein, *elastomucin*. It is probable that many of the earlier studies

on "elastin" were really investigations on a mixture of elastin and elastomucin.<sup>2</sup>

3. KERATINS are proteins resistant to digestion by pepsin and trypsin, and insoluble in dilute acids and alkalies, in water, and in organic solvents. Keratins have been divided into two classes: (a) *Eukeratins* (true or hard

Courtesy, K. G. Stern and C. V. Tondo, unpublished data.

keratins) are keratins which on hydrolysis yield histidine, lysine, and arginine in a molecular ratio of approximately 1:4:12,<sup>3</sup> and (b) *pseudo-keratins* (false or soft keratins) are a heterogeneous group of insoluble proteins which are digestible with difficulty, and which do *not* yield histidine, lysine, and arginine in the molecular ratio of 1:4:12.

**Histones** are soluble in water and insoluble in dilute ammonia, and, in the absence of ammonium salts, insoluble even in excess of ammonia. They yield precipitates with solutions of other proteins and a coagulum on heating which is easily soluble in very dilute acids. On hydrolysis they

<sup>2</sup> Hall, Reed, and Tunbridge: *Nature*, **170**, 264 (1952).

<sup>3</sup> Since the development of better methods for the analysis of amino acids, these numerical values have changed but the principle still is valid.

yield a large number of amino acids, among which arginine predominates. Histones contain tyrosine but appear to be lacking in tryptophan. In short, histones are basic proteins which stand between protamines and true proteins; e.g., scombrone from mackerel sperm, thymus histone.

**Globins** are simple basic proteins which were at one time classed as histones because of similarities in solubility, etc. The globins differ from the histones, however, in isoelectric point, toxicity, and amino acid composition. Histones are high in arginine and isoleucine and contain only traces of tryptophan, but globins contain average quantities of arginine and tryptophan and are unique in their high content of histidine and deficiency in isoleucine. Globins are usually found in nature as the protein portion of conjugated proteins, e.g., globin from hemoglobin.

**Protamines** are simpler polypeptides than the proteins included in the preceding groups. Their acid salts are soluble in water, uncoagulable by heat, have the property of precipitating aqueous solutions of other proteins, possess strong basic properties, and form stable salts with strong mineral acids. They yield comparatively few amino acids, among which the basic ones, especially arginine, predominate. They are the simplest natural proteins; e.g., salmine from salmon sperm, sturine from sturgeon sperm, clupeine from herring sperm, scombrine from mackerel sperm.

## II. CONJUGATED PROTEINS

The conjugated proteins, like the simple proteins, are substances which may be isolated from biological materials by suitable methods. They differ from the simple proteins, however, in the fact that the intact molecule consists of protein combined with some nonprotein substance (the prosthetic group) in a manner which confers new and characteristic properties on the complex formed. They are classified according to the nature of the prosthetic group, as indicated below.

**Nucleoproteins.** Compounds of one or more protein molecules with nucleic acids. The nucleic acid of the cell nucleus appears to be deoxyribose nucleic acid which is united to the protamines, histones, and other basic proteins of the cell nucleus. The nucleoproteins of the cytoplasm yield ribose nucleic acid; the nature of the protein component awaits investigation.

**Glycoproteins.** Mucins contain a uronic acid (see Chapter 2) probably united in salt linkage to the basic groups of proteins. They are found in vitreous humor and in Wharton's jelly of the umbilical cord.

Mucoids do not contain a uronic acid but consist of protein firmly bound to a polysaccharide such as polymerized glucosamine-mannose; e.g., serum mucoid, ovomucoid.

Sulfomucins contain sulfuric acid, uronic acid, and either chondrosamine or glucosamine. They are found in cartilage, intestinal tissue, cornea, gastric mucosa.

**Phosphoproteins.** Compounds of the protein molecule with phosphoric acid other than a nucleic acid or lecithin;<sup>4</sup> e.g., casein from milk, ovovitellin from egg yolk, and other proteins associated with the feeding

---

<sup>4</sup> The accumulated chemical evidence distinctly points to the propriety of classifying the phosphoproteins as conjugated compounds, i.e., they are esters of phosphoric acid (or acids) and protein.

of the young. In the cell nucleus there are phosphoproteins the composition of which is still under investigation.

**Chromoproteins** are compounds of proteins with a metal-containing prosthetic group, e.g., the red iron-containing hemoglobins ( $\text{Fe} = 0.34$  per cent) from vertebrate blood; the blue copper-containing hemocyanins from the blood of certain invertebrates; the green magnesium-containing chlorophyll proteins from plants, etc. The protein should not be regarded as a mere colloidal carrier of the prosthetic group, but as an integral portion of the chromoprotein molecule, determining not only the magnitude but even the nature of the reaction it promotes. Thus one iron-containing prosthetic group combined with four different proteins gives rise to four different substances: methemoglobin, catalase, peroxidase, and a cytochrome ( $\text{Fe} = 0.43$  per cent).

**Lipoproteins** are compounds of the protein molecule with lecithins, cholesterol, etc.

**Metalloproteins** are various protein enzymes which contain metals as an inherent portion of their molecule. Thus, tyrosinase contains copper, arginase contains manganese or magnesium, whereas zinc is present in carbonic anhydrase, and molybdenum in xanthine oxidase.

### III. DERIVED PROTEINS

#### PRIMARY PROTEIN DERIVATIVES

The primary protein derivatives are substances formed from some of the simple and conjugated proteins on denaturation. When these proteins are subjected to certain chemical and physical agents they undergo intramolecular changes which are accompanied by changes in the properties of the original material. Although the nature of these intramolecular changes is still unknown, they may be recognized by the characteristic properties of the substances formed, as indicated in the classification below.

**Proteans** are insoluble products which apparently result from the incipient action of water, very dilute acids, or enzymes—e.g., fibrin from fibrinogen, myosan from myosin, edestan from edestin. This is probably an early denaturation stage.

**Metaproteins** are products of the action of dilute acids and alkalis whereby the molecule is so far altered as to form products soluble in weak acids and alkalis but insoluble at their isoelectric points; e.g., acid metaprotein (acid albuminate), alkali metaprotein (alkali albuminate).

**Coagulated proteins** are insoluble products which result when isoelectric solutions of the protein are denatured by (1) heat, (2) alcohol, (3) ultraviolet light, (4) ultrasonic waves, (5) mechanical shaking, (6) mineral acids and alkalis, (7) grinding, (8) neutral chemical agents, etc.

#### SECONDARY PROTEIN DERIVATIVES<sup>5</sup>

The secondary protein derivatives are substances formed during the hydrolysis of the protein molecule. As hydrolysis proceeds the intact

<sup>5</sup> The term secondary protein derivatives is used because their formation may be preceded by that of some of the primary derivatives.

molecule is split up into a series of smaller and smaller fragments which are designated, respectively, as primary and secondary proteoses, peptones, and peptides. The substances in each group are not homogeneous chemical entities, but rather mixtures of fragments of the original protein which probably vary in both composition and size and which are grouped together merely because they exhibit certain characteristic properties in common. This classification has little modern significance and it is being gradually abandoned except for the peptides.

**Primary proteoses** are soluble in water, noncoagulable by heat, precipitated by concentrated nitric acid, and precipitated by half-saturation with ammonium sulfate.

**Secondary proteoses** are soluble in water, noncoagulable by heat, and precipitated by saturating their solutions with ammonium sulfate.

**Peptones** are soluble in water, noncoagulable by heat, and not precipitated by saturating their solutions with ammonium sulfate.

**Peptides** are definitely characterized combinations of two or more amino acids, the carboxyl group of one being united with the amino group of the other with the elimination of a molecule of water,<sup>6</sup>—e.g., dipeptides, tripeptides, tetrapeptides, pentapeptides, etc.

## CONSIDERATION OF VARIOUS CLASSES OF PROTEINS

### I. SIMPLE PROTEINS

#### A. ALBUMINS

Albumins constitute the first class of simple proteins and may be defined as simple proteins which are coagulable by heat and soluble in pure (salt-free) water. They are also soluble in salt solutions and those of animal origin are not precipitated upon saturating their solutions at 30°C. with sodium chloride or magnesium sulfate except in the vicinity of their isoelectric points. All albumins of animal origin are soluble in half-saturated ammonium sulfate solution<sup>7</sup> but may be precipitated by increasing the salt concentration up to full saturation. They may also be thrown out of solution by the addition of a sufficient quantity of a mineral acid. Metallic salts also possess the property of precipitating albumins, some of the precipitates being soluble in excess of the reagent, whereas others are insoluble in such an excess. Many albumins have been obtained in crystalline form, notably egg and serum albumins from various species.

### EXPERIMENTS ON ALBUMINS

Besides the general protein color reactions and precipitation reactions described in the previous chapter, the albumins have other properties which are used to identify proteins belonging to this class. Some of these properties are illustrated by the following experiments:

<sup>6</sup> The peptones are undoubtedly peptides or mixtures of peptides, the latter term being at present used to designate those of definite structure.

<sup>7</sup> In this connection Osborne's observation is of interest, namely that certain vegetable albumins are precipitated by saturating their solutions with sodium chloride or magnesium sulfate or by half-saturating with ammonium sulfate.

**1. Solubility in Concentrated Salt Solutions.** (a) Place 25 ml. of dilute egg albumin solution (prepared as described on p. 169) in a beaker and add 6.6 g. of solid ammonium sulfate. Stir until dissolved. The solution is now 2 M in ammonium sulfate, or approximately half-saturated. Is the albumin precipitated? Now add an excess of solid ammonium sulfate and stir to produce full saturation with the salt. What happens? Dilute a small portion of the mixture with distilled water. Is the effect of ammonium sulfate reversible? Filter the remainder of the mixture. Test the precipitate by Millon's test. Test the filtrate for protein by the biuret test, using saturated ammonium sulfate solution as a control. What are your conclusions?

(b) To a 25-ml. portion of egg albumin solution in a beaker add an excess of solid sodium chloride and stir until the solution is saturated with the salt. How does the result differ from that with ammonium sulfate? Add 2 to 3 drops of acetic acid. What occurs? Explain.

**2. Heat Coagulation.** Add 3 to 5 drops of acetic acid to 25 ml. of dilute egg albumin solution in a small evaporating dish and heat to boiling. What happens? Why is the acetic acid added? Test a portion of the coagulum by Millon's reaction. Explain.

## B. GLOBULINS

Globulins are simple proteins present in blood serum, muscle, and other animal tissues, and also present in many plant seeds. They give all the ordinary protein tests and are coagulable by heat. Globulins differ from the albumins in being insoluble in pure (salt-free) water. They are, however, soluble in neutral solutions of the *salts* of strong acids with strong bases, such as sodium chloride. The globulins require a certain concentration of salt in order that they may remain in solution, precipitating when the concentration of salt is lowered by such processes as dilution or dialysis. In general the globulins are precipitated by half-saturation of their solutions with ammonium sulfate—i.e., by the addition to their solutions of an equal volume of saturated ammonium sulfate solution.<sup>8</sup> Most globulins are also precipitated from their solutions by saturation with solid sodium chloride or magnesium sulfate.

Blood serum apparently contains a variety of globulins, characterized by differences in solubility, in precipitability by ammonium or sodium sulfate, and in rate of electrophoretic migration (Chapter 22). Blood globulins have not yet been crystallized but crystalline globulins have been obtained from milk ( $\beta$ -lactoglobulin), muscle (myosin), gastric juice (pepsin), and numerous plant seeds.

---

<sup>8</sup> It is generally stated that globulins are precipitated from their solutions upon half-saturation with ammonium sulfate and that albumins are precipitated upon complete saturation by this salt. Comparatively few exceptions were found to this rule until proteins of vegetable origin came to be more extensively studied. These studies, furthered especially by Osborne and associates, have demonstrated very clearly that the characterization of a globulin as a protein which is precipitated by half-saturation with ammonium sulfate can no longer hold. Certain vegetable globulins have been isolated which are not precipitated by this salt until a concentration is reached greater than that secured by half-saturation. As an example of an albumin which does not conform to the definition of an albumin as regards its precipitation by ammonium sulfate may be mentioned the leucosin of the wheat germ, which is precipitated from its solution upon half-saturation with ammonium sulfate. The limits of precipitation by ammonium sulfate, therefore, do not furnish a sufficiently accurate basis for the differentiation of globulins from albumins.

We have used an albumin of animal origin (egg albumin) for all the protein tests thus far, whereas the globulin to be studied will be prepared from a vegetable source. The vegetable globulin we shall study may be taken as a type of all globulins, both animal and vegetable.

## EXPERIMENTS ON GLOBULIN

**Preparation of Edestin.** Extract 20 to 30 g. (a handful) of crushed hemp seed with about 150 ml. of 10 per cent sodium chloride solution for one-half hour at 60° C. Filter while hot through a filter paper moistened with 10 per cent sodium chloride solution into a 600-ml. beaker. To the warm filtrate, carefully add distilled water heated to 60° C. until the solution just becomes

FIG. 58. EDESTIN.

turbid (300 to 500 ml. of water are required, depending upon the concentration of the protein). Warm the solution in a water bath at 60° until it becomes clear and then permit both the solution and the water bath to cool spontaneously at room temperature. In 24 hours there settles out a precipitate of globulin which is almost entirely crystalline in form. This particular globulin in hemp seed is called edestin. It is soluble in warm 10 per cent sodium chloride solution and may be crystallized by cooling its solution, or by dialyzing the solution against distilled water. Addition of warm water, as above, increases the yield of crystals obtained by decreasing the solubility of the protein. Edestin crystallizes in several different forms, chiefly octahedra (see Fig. 58). Filter off the edestin and make the following tests on the crystalline material.

### *Tests on Crystallized Edestin.*

1. *Microscopical Examination* (see Fig. 58).
2. *Solubility.* Try the solubility in water, 1 per cent sodium chloride solution, dilute acid and alkali, and alcohol.
3. *Millon's Reaction.*

4. *Coagulation Test.* Place a small amount of the globulin in a test tube, add a little water, and boil. Now add hydrochloric acid and note that the protein no longer dissolves. It has been coagulated.

Dissolve the remainder of the edestin in about 50 ml. of 10 per cent sodium chloride solution, and make the following tests on this solution.

#### *Tests on Edestin Solution.*

1. *Influence of Protein Precipitants.* Try a few protein precipitants such as nitric acid, tannic acid, picric acid, and mercuric chloride. Compare with the results on egg albumin (p. 174). Can you distinguish between albumin and globulin by tests such as these?

#### 2. *Biuret Test.*

3. *Coagulation Test.* Boil some of the solution in a test tube. What happens?

4. *Saturation with Sodium Chloride.* Saturate about 10 ml. of the solution with solid sodium chloride. How does this result differ from that obtained upon saturating egg albumin solution with solid sodium chloride?

5. *Precipitation by Dilution.* Add a few drops of the solution to a test tube filled with distilled water. Why does the globulin precipitate?

6. *Precipitation by Dialysis.* Place the remainder of the solution in a dialyzing bag and dialyze against about 500 ml. of distilled water. Why does the globulin precipitate? Examine the precipitate under the microscope.

### C. GLUTELINS

It has been repeatedly shown, particularly by Osborne, that after extracting the seeds of cereals with water, neutral salt solution, and strong alcohol, there still remains a residue which contains protein material which may be extracted by very dilute acid or alkali. These probably denatured proteins which are insoluble in all neutral solvents, but readily soluble in very dilute acids and alkalies, are called glutelins. The only member of the group which has yet received a name is the glutenin of wheat,<sup>9</sup> a mixture of proteins which constitutes nearly 50 per cent of the gluten, the remainder being principally gliadin.

*Gluten: Preparation and Tests.* To about 50 g. of wheat flour in a casserole or evaporating dish add a little water and mix thoroughly until a stiff dough results. Knead this dough thoroughly and permit it to stand for about half an hour. This is done in order that the maximum quantity of gluten may be obtained. Treat the dough with about 200 ml. of water and knead it thoroughly. Note the yellowish color of the dough and the milky appearance of the water due to suspended starch granules. (Place a drop of the suspension on a slide, cover with a cover slip, run underneath the slip a drop of iodine solution and observe the stained starch granules under the microscope.)

<sup>9</sup> Work by Blish and Sandstedt indicates that glutenin prepared by extraction of gluten with dilute alkali is actually an irreversible alteration product of a more complex protein in the crude gluten.

Filter and apply a protein color reaction (see p. 169) to the filtrate. It should be positive, indicating that water-soluble proteins were present in the flour. Add fresh water to the dough and repeat the kneading process. Continue this procedure with fresh addition of water, or holding the gluten under the tap, until practically no starch granules are noted in suspension. To a small piece of the yellow, fibrous gluten apply Millon's reaction (p. 169). This test shows gluten to be protein material. Utilize the remainder of the gluten in the preparation of gliadin below.

**Glutenin: Preparation and Tests.** (In the preparation of gliadin below it is customary to remove this prolamin from the crude gluten by extracting with 70 per cent alcohol. Inasmuch as gluten consists chiefly of gliadin and glutenin the portion of the gluten remaining after the extraction of the alcohol-soluble protein gliadin may be utilized for the preparation of glutenin.)

To the finely divided residue from the preparation of gliadin below in a flask or bottle add about 250 ml. of 70 per cent alcohol. Allow to stand for about 48 hours with repeated shaking in order to remove any remaining gliadin. Crude glutenin remains. To purify the glutenin, treat it in a mortar with sufficient 0.2 per cent NaOH to dissolve it, and filter the liquid through a wet pleated filter. Neutralize the filtrate carefully with 0.2 per cent HCl, adding the acid drop by drop with thorough mixing after each addition. (The glutenin is soluble in excess of acid.) Filter off the glutenin precipitate and wash several times with 70 per cent alcohol and finally with water. Apply the following tests:

1. Solubility in water, 0.9 per cent NaCl solution, 0.2 per cent HCl, and 0.5 per cent  $\text{Na}_2\text{CO}_3$ .
2. Millon's Reaction.

#### D. PROLAMINS (ALCOHOL-SOLUBLE PROTEINS)

The term prolamin was proposed by Osborne for the group of plant proteins formerly termed "alcohol-soluble proteins." The name is very appropriate inasmuch as these proteins yield, upon hydrolysis, especially large amounts of proline and ammonia. The prolamins are simple proteins which are insoluble in water, absolute alcohol, and other neutral solvents, but are soluble in 70 to 80 per cent alcohol and in dilute acids and alkalies. They occur widely distributed, particularly in the vegetable kingdom, and include zein of maize, hordein of barley, gliadin of wheat and rye, bynin of malt, and kafirin of kafir. Sorghum and rice also contain alcohol-soluble proteins. They yield relatively large amounts of glutamic acid on hydrolysis but little or no lysine. The largest percentage of glutamic acid (47 per cent) ever obtained as a decomposition product of a protein substance was obtained from the hydrolysis of the prolamin gliadin. This yield of glutamic acid is also the largest amount of any single decomposition product yet obtained from any protein except the 88.4 per cent of arginine obtained from salmin.

**Gliadin: Preparation and Tests.** Introduce the finely divided crude gluten as prepared on p. 190 into a flask or bottle, add about 250 ml. of 50 to 70 per cent alcohol, and allow the mixture to stand 24 hours with occasional shaking. Filter (retaining the undissolved portion for preparation of glutenin, above) and evaporate the filtrate to dryness in a porcelain dish over a water

bath. Pulverize the dry material. Apply the following tests to this gliadin powder:

**Solubility and Protein Tests.** Test the solubility in alcohol (30 per cent, 50 per cent, and 70 per cent), water, 0.9 per cent NaCl, 0.2 per cent HCl, and 0.5 per cent Na<sub>2</sub>CO<sub>3</sub>. Shake each tube repeatedly and filter. To the filtrate apply the coagulation test (p. 190) and the biuret test (p. 171).

### E. ALBUMINOIDS (SCLEROPROTEINS)

The albuminoids yield hydrolytic products similar to those obtained from the other simple proteins already considered, thus indicating that they possess essentially the same chemical structure. They differ from all other proteins, whether simple, conjugated, or derived, in that they are insoluble in all neutral solvents. The albuminoids include "the principal organic constituents of the skeletal structure of animals as well as their external covering and its appendages." Some of the principal albuminoids are keratins from hair, horn, nails, feathers, etc.; elastins from arteries, ligaments; collagens from bone, skin, hoof, etc.; reticulin, spongin, and silk fibroin. Gelatin cannot be classed as an albuminoid although it is a transformation product of collagen. The various albuminoids differ from each other in certain fundamental characteristics (see p. 183). Experiments on albuminoids will be found in Chapter 9.

## II. CONJUGATED PROTEINS

Conjugated proteins consist of a protein molecule united to some non-protein molecule or molecules otherwise than as a salt. Glycoproteins, nucleoproteins, chromoproteins, phosphoproteins, lipoproteins, and metalloproteins are the six classes of conjugated proteins.

**Glycoproteins** may be considered as compounds of the protein molecule with a substance or substances containing a carbohydrate group other than a nucleic acid. They yield, upon decomposition, protein and carbohydrate derivatives, notably glucosamine, CH<sub>2</sub>OH·(CHOH)<sub>3</sub>-CH(NH<sub>2</sub>)·CHO, galactosamine, galactose, fucose, and uronic acids. The principal glycoproteins are (1) mucoids, (2) mucins, and (3) sulfomucins. The elementary composition of typical mucoids is as follows:

|                  | <i>N</i> | <i>S</i> | <i>C</i> | <i>H</i> | <i>O</i> |
|------------------|----------|----------|----------|----------|----------|
| Tendomucoid..... | 11.75    | 2.33     | 48.76    | 6.53     | 30.60    |
| Osseomucoid..... | 12.22    | 2.32     | 47.43    | 6.63     | 31.40    |

(For the preparation of tendomucoid see Chapter 9; of salivary mucin, see Chapter 13.) Amyloid,<sup>10</sup> which appears pathologically in the spleen, liver, and kidneys, is also a glycoprotein.

<sup>10</sup> Not to be confused with the substance amyloid, which may be formed from cellulose (see p. 90).

**Phosphoproteins** are considered to be compounds of the protein molecule and phosphoric acid. The percentage of phosphorus in phosphoproteins is very similar to that in nucleoproteins, but they differ from this latter class of proteins in that they do not yield any purine bases upon hydrolytic cleavage. Two of the common phosphoproteins are the casein of milk and the ovovitellin of egg yolk. The phosphorus in these proteins exists in phosphoric acid radicals bound in ester linkage to the hydroxy amino acids serine and threonine. For the preparation of a typical phosphoprotein (casein), see Chapter 8.

**Chromoproteins** are compounds of the protein molecule with a metalloporphyrin (see Chapter 22) or some similar substance. The principal members of the group are the hemoglobin of the blood and the chlorophyll proteins of plants. Upon hydrolytic cleavage, hemoglobin yields a protein termed globin and a coloring matter which contains iron and is known as heme. Hemocyanin, another member of the class of chromoproteins, occurs in the blood of certain invertebrates, notably cephalopods, gasteropods, and crustacea. Hemocyanin generally contains either copper, manganese, or zinc, as contrasted to the iron of the hemoglobin molecule. For the preparation of hemoglobin in crystalline form, see Chapter 22.

**Lipoproteins** consist of a protein molecule joined to lecithin, cholesterol, and other fatty substances. They have been comparatively little studied and may possibly be mixtures of protein and lipide material. These unions are not split by treatment with ether but are by alcohol, especially after heat denaturation of the protein.

**Nucleoproteins.** For consideration of nucleoproteins, see Chapter 7.

**Metalloproteins.** Numerous protein enzymes contain metals as an inherent portion of their molecules; e.g., carbonic anhydrase is a zinc protein complex, arginase contains manganese or magnesium, tyrosinase contains copper, etc.

### III. DERIVED PROTEINS

#### A. PRIMARY PROTEIN DERIVATIVES

##### 1. PROTEANS

Proteans are those insoluble, denatured protein substances which are produced from proteins originally soluble through the incipient action of water, enzymes, very dilute acids, etc. According to Osborne nearly all proteins may give rise to proteans, and the determining factor in the transformation is the hydrogen-ion concentration. The protean produced from the transformation of edestin is called edestan; that produced from myosin is called myosan, etc. The name protean was first given to this class of proteins by Osborne in 1900 in connection with his studies of edestin. It is but little used at present.

##### 2. METAPROTEINS

The metaproteins are denatured proteins formed by the action of dilute acids and alkalies on some proteins, especially on the albumins and the globulins. The conversion of protein into metaprotein is accelerated by a

rise in temperature, taking place almost immediately at the boiling point. There is, at present, no definite evidence concerning the exact nature of the changes which the protein molecule undergoes during this transformation. (See the section "Protein Denaturation and Its Reversal" in Chapter 5.) The denatured protein behaves like a suspensoid, dissolving in dilute acids and alkalis—i.e., when the particles are electrically charged—and flocculating when the solutions are brought to the isoelectric point. The suspensoid character of the metaproteins is also indicated by their sensitivity to electrolytes, especially in the neighborhood of the isoelectric point. The metaproteins are precipitated by saturation of their solutions with ammonium sulfate and, when dissolved in acid, by full saturation with sodium chloride. Boiling an isoelectric suspension of metaprotein converts it into coagulated protein, in which case the material is no longer soluble in dilute acids and alkalis.

The metaproteins are usually classified as (1) acid metaproteins, or so-called acid albuminates, and (2) alkali metaproteins, or alkali albuminates, depending upon whether they are formed by the action of acid or alkali on the native protein. Transformation products with similar physical properties are formed by the action of enzymes, ultraviolet light, etc., on native protein. It is unlikely that these procedures ever produce a homogeneous metaprotein.

## EXPERIMENTS ON A DENATURED PROTEIN

**Preparation and Study: Alkali Metaprotein (Alkali Albuminate).** Carefully separate the white from the yolk of a hen's egg and place the former in an evaporating dish. Add 10 per cent sodium hydroxide solution, drop by drop, stirring continuously. The mass gradually thickens and finally assumes the consistency of jelly. This is solid alkali metaprotein or "Lieberkühn's jelly." Do not add an excess of sodium hydroxide or the jelly will dissolve. Cut it into small pieces, place a cloth or wire gauze over the dish, and by means of running water, wash the pieces free from adherent alkali. Now add a small amount of water, which forms a weak alkaline solution with the alkali within the pieces, and dissolve the jelly by gentle heat. Cool the solution and divide it into two parts. Proceed as follows with the first part: Neutralize with dilute hydrochloric acid, noting the odor of the liberated hydrogen sulfide as the alkali metaprotein precipitates. Filter off the precipitate and test as follows:

1. **Solubility.** Solubility in water, sodium chloride solution, dilute acid, and alkali.

2. **Millon's Reaction.**

3. **Coagulation Test.** Suspend a little of the metaprotein in water (neutral solution) and heat to boiling for a few moments. Now add 1 to 2 drops of dilute NaOH solution to the water and see if the metaprotein is still soluble in dilute alkali. What is the result and why?

4. **Test for Cystine and Cysteine Sulfur** (see p. 168).

Subject the second part of the original solution to the following tests:

5. **Coagulation Test.** Heat some of the solution to boiling in a test tube. Does it coagulate?

### 6. *Biuret Test.*

7. *Influence of Protein Precipitants.* Try a few protein precipitants such as picric acid and mercuric chloride. How do the results obtained compare with those from the experiments on egg albumin? (See p. 174.)

## 3. COAGULATED PROTEINS

Simple proteins, such as the albumins and globulins, are converted by heat, ultraviolet light, mechanical agitation, or long contact with alcohol, etc., into insoluble materials known as coagulated proteins, which probably consist of the matting together of the denatured protein fibrils similar to the formation of felt from short fibers of hair. (See p. 156 and the section "Protein Denaturation and Its Reversal" in Chapter 5.) Coagulated proteins are insoluble in water, salt solutions, and dilute acids and alkalies. They are soluble in strong mineral acids and alkalies which hydrolyze the protein into simpler substances.

## EXPERIMENTS ON COAGULATED PROTEIN

Ordinary coagulated egg white may be used in the following tests:

1. *Solubility.* Try the solubility of small pieces of coagulated protein in water, 1 per cent sodium chloride, and dilute and concentrated acid and alkali.

2. *Millon's Reaction.*

3. *Xanthoproteic Reaction.* Partly dissolve a medium-sized piece of the protein in concentrated nitric acid. Cool the solution and carefully add an excess of ammonium hydroxide. Both the protein solution and the undissolved protein will be colored orange.

4. *Biuret Test.* Partly dissolve a medium-sized piece of the protein in concentrated sodium hydroxide solution. If the proper dilution of copper sulfate solution is now added, the white coagulated protein, as well as the protein solution, will assume the characteristic purplish-violet color.

## B. SECONDARY PROTEIN DERIVATIVES

### 1. PROTEOSES AND PEPTONES

The proteoses and peptones are poorly defined intermediate products formed during the digestion of proteins by the proteolytic enzymes, as well as in the decomposition of proteins by hydrolysis and the putrefaction of proteins through the action of bacteria. As hydrolysis proceeds, the large, colloidal protein molecule is split up into a mixture of large and small fragments which were formerly designated as primary and secondary proteoses, peptones, and peptides. The larger fragments are constantly being broken down until, finally, only amino acids remain. It should be emphasized that the substances formerly known as proteoses and peptones are not homogeneous chemical entities, but rather mixtures of fragments of the original protein molecule which vary in composition and also in size, and are grouped together merely because they exhibit

certain characteristic properties in common. Those fragments which are precipitated when the solution is half-saturated with ammonium sulfate were known as primary proteoses; those precipitated when the solution is saturated with ammonium sulfate were called secondary proteoses. The peptones were not precipitated by ammonium sulfate. The proteoses still exhibit colloidal properties, but these properties become less pronounced and begin to disappear entirely by the time the breakdown of the protein molecule has reached the peptone stage. Thus, in addition to being nonprecipitable by ammonium sulfate, the peptones diffused through such membranes as collodion and failed to give some of the characteristic precipitation reactions of proteins.

Since the proteoses and peptones are both heterogeneous mixtures of fragments of the original protein molecules, different preparations of these substances will show variations in composition and properties depending upon the nature of the protein used as starting material, the method of hydrolysis employed, and the method used to separate the various products of hydrolysis. Thus the so-called peptones sold commercially vary not only in composition but also in the amounts of primary and secondary proteoses they contain. As a class the proteoses and peptones are a mixture of amino acids and peptides not coagulated by heat. Some are also soluble in dilute alcohol. *Peptones differ from proteoses in being more diffusible, and nonprecipitable by  $(\text{NH}_4)_2\text{SO}_4$ , and by their failure to give any reaction with potassium ferrocyanide and acetic acid, potassium-mercuric iodide and HCl, picric acid, and trichloroacetic acid.* Peptones may be precipitated by phosphotungstic acid, phosphomolybdic acid, absolute alcohol, and tannic acid, but an excess of the precipitant may dissolve the precipitate. The so-called primary proteoses, being relatively large molecules, are precipitated by  $\text{HNO}_3$  and are the only members of the proteose-peptone group which are so precipitated.

## EXPERIMENTS ON PROTEOSES AND PEPTONES

Some of the more general characteristics of the proteose-peptone group may be noted by making the following simple tests on a proteose-peptone powder:

**1. Solubility.** Solubility in hot and cold water and sodium chloride solution.

**2. Millon's Reaction.**

**3. Precipitation by Picric Acid.** To 5 ml. of proteose-peptone solution in a test tube add picric acid until a permanent precipitate forms. The precipitate disappears on heating and returns on cooling.

**4. Precipitation by a Mineral Acid.** Try the precipitation by nitric acid.

**5. Coagulation Test.** Heat a little proteose-peptone solution to boiling. Does it coagulate like the other simple proteins studied?

SEPARATION OF PROTEOSES AND PEPTONES<sup>11</sup>

Place 50 ml. of proteose-peptone solution in an evaporating dish or casserole, and half-saturate it with ammonium sulfate solution, which may be accomplished by adding an equal volume of saturated ammonium sulfate solution. At this point note the appearance of a precipitate of the primary proteoses. Now heat the half-saturated solution and its suspended precipitate to boiling and saturate the solution with solid ammonium sulfate. At full saturation the secondary proteoses are precipitated. The peptones remain in solution.

Proceed as follows with the precipitate of proteoses: Collect the sticky precipitate on a rubber-tipped stirring rod or remove it by means of a watch glass to a small evaporating dish and dissolve it in a little water. To remove the ammonium sulfate, which adhered to the precipitate and is now in solution, add barium carbonate, boil, and filter off the precipitate of barium sulfate. Concentrate the proteose solution to a small volume<sup>12</sup> and make the following tests:

*Tests on Proteoses.**1. Biuret Test.*

*2. Precipitation by Nitric Acid.* What would a precipitate at this point indicate?

*3. Precipitation by Trichloroacetic Acid.* This precipitate dissolves on heating and returns on cooling.

*4. Precipitation by Picric Acid.* This precipitate also disappears on heating and returns on cooling.

*5. Precipitation by Potassio-mercuric Iodide and Hydrochloric Acid.*

*6. Coagulation Test.* Boil a little in a test tube. Does it coagulate?

*7. Precipitation by Acetic Acid and Potassium Ferrocyanide.*

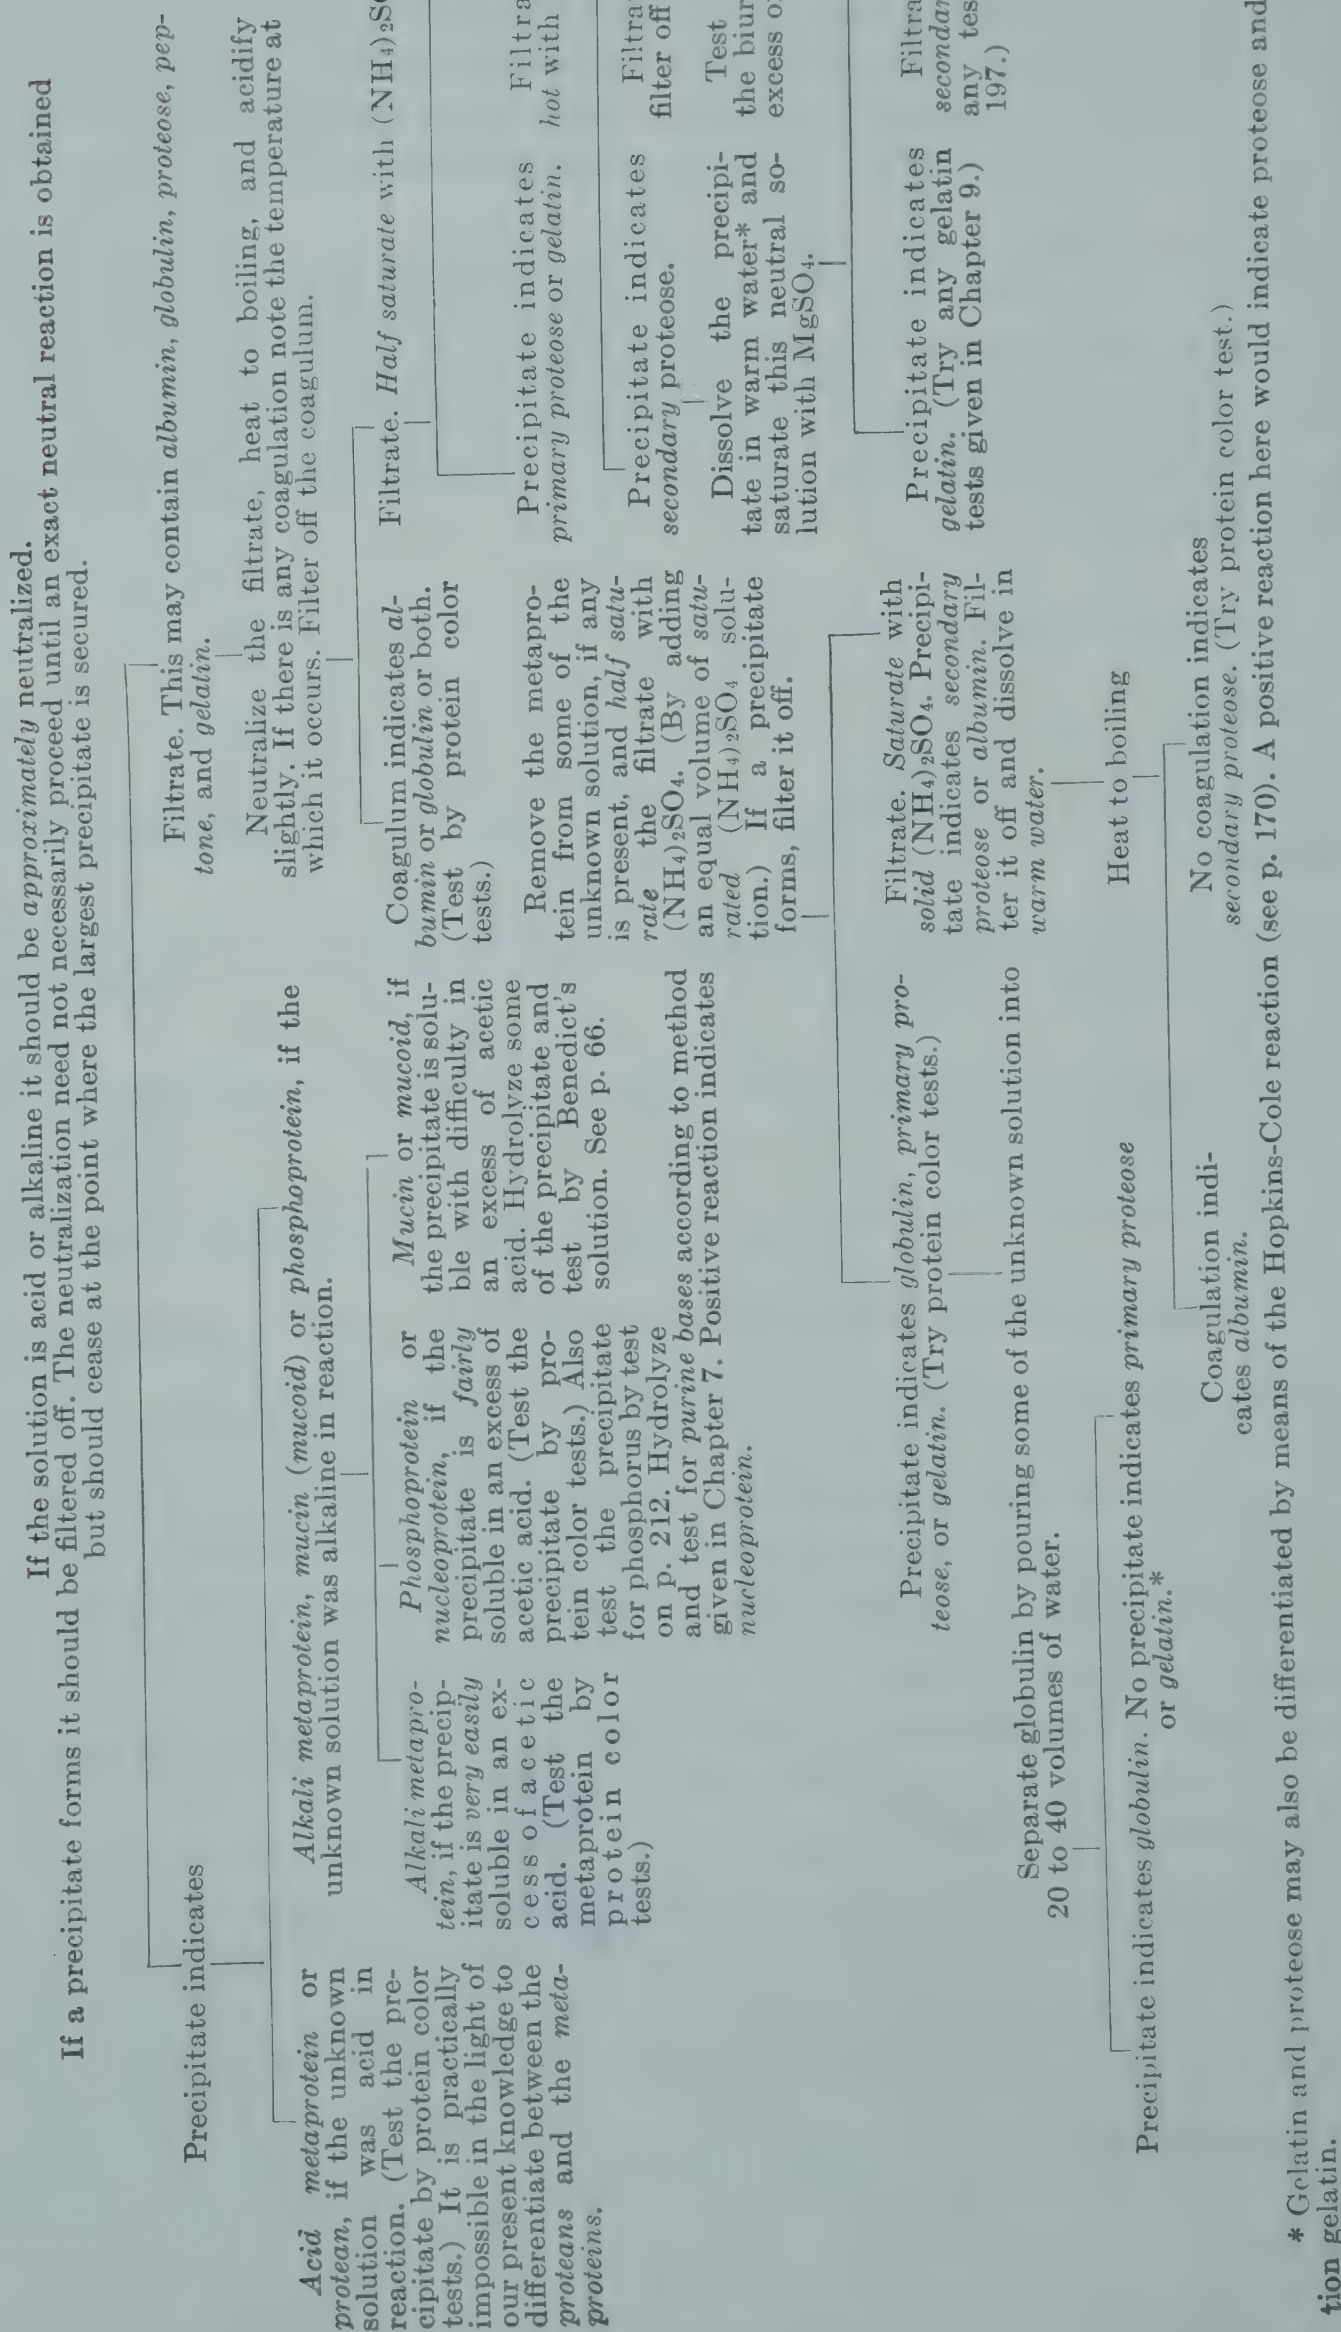

*Tests on Peptones.* The solution containing the peptones should be cooled and filtered, and the ammonium sulfate in solution removed by boiling with barium carbonate as described above. After filtering off the barium sulfate precipitate in the presence of a filter aid such as diatomaceous earth, concentrate the peptone filtrate to a small volume and repeat the tests as given under the proteose solution, above. Also try the precipitation by tannic acid. In the biuret test the solution should be made very strongly alkaline with solid potassium hydroxide.

<sup>11</sup> The separation of proteoses and peptones by means of fractional precipitation with ammonium sulfate does not possess the significance it was once supposed to possess inasmuch as the boundary between these substances and peptides is not well defined (see p. 113). For discussion of a quantitative method for determining protein and proteose based on their separation by trichloroacetic acid, see Seibert: *J. Biol. Chem.*, **70**, 265 (1926).

<sup>12</sup> If the proteoses are desired in powder form, this concentrated proteose solution may now be precipitated by alcohol or acetone, and this precipitate, after being washed with acetone and with ether, may be dried and powdered.

## SCHEME FOR DETECTION OF PROTEINS

MODEL CHART FOR REVIEW PURPOSES

| Protein            | Solubility |           |           |                                       |           |           | Protein Color Test | Precipitation Tests              |                                    |         |                                 |                                |             | Salting-out Tests    |                                                 | Diffusion | Coagulation by Heat |
|--------------------|------------|-----------|-----------|---------------------------------------|-----------|-----------|--------------------|----------------------------------|------------------------------------|---------|---------------------------------|--------------------------------|-------------|----------------------|-------------------------------------------------|-----------|---------------------|
|                    | Water      | 10 % NaCl | 0.2 % HCl | 0.5 % Na <sub>2</sub> CO <sub>3</sub> | Conc. HCl | Conc. 2. PEPTIDES

The peptides are “definitely characterized combinations of two or more amino acids, the carboxyl (COOH) group of one being united with the amino (NH<sub>2</sub>) group of the other with the elimination of a molecule of water.” These peptides are more fully discussed on pp. 113 and 152.

REVIEW OF PROTEINS

In order to facilitate the student’s review of the proteins, the preparation of a chart similar to the model shown above is recommended. The signs + and – may be conveniently used to indicate positive and negative reactions.

## Nucleic Acids and Nucleoproteins

Nucleoproteins owe their name to the fact that the first representatives of this class of conjugated proteins were obtained from cell nuclei. In the 1870's the Swiss chemist, Miescher, influenced by the growing importance of the nucleus in the cell theory, began the investigation of its composition and recognized a new type of compound which he termed *Nucleinstoff*. This proved to be a conjugate of protein and an acidic material of high molecular weight now known as nucleic acid. It has developed that compounds of this general chemical type are far more widely distributed than the name implies.

**Distribution.** Two major types of nucleic acid are now recognized in all cells, whether plant, animal, or bacterial. These are generally differentiated by the kind of carbohydrate present, *2-deoxypentose* or *pentose*. In normal cells the *deoxypentose nucleic acid* is found only in the nucleus in association with the chromosomal material, and probably is the only substance truly deserving the name *nucleic acid* in the sense implied by Miescher. The bulk of the *pentose nucleic acids* are in the cytoplasm. Small amounts of pentose nucleic acids are also present in the nucleus, both in the nucleoli and in the chromosomal material as isolated by the procedures of Mirsky.

Cytochemical and biological developments of the last two or three decades have focused attention on the overwhelming circumstantial evidence which associates deoxypentose nucleic acid with the morphological forms recognized as the chromosomes. The facts that viruses and bacteriophages have invariably proved to contain one or both types of the nucleoproteins, and that the simplest ones are pure crystalline nucleoproteins, have pointed to some unique function of nucleoproteins in directing growth and reproductive processes. Of special significance are certain substances which have the property of bringing about an inheritable alteration (mutation) of living bacteria, such as that from pneumococcus type II rough to type III smooth. These agents, the *transforming factors*, exhibit the kind of ability which is usually associated only with genes. In some instances such substances have been shown to be essentially pure deoxypentose nucleic acid.

**Characteristics of Nucleoproteins.** In all cases the nucleic acids have been found to be associated with protein. In some of the pentose nucleoproteins the association is very firm and appears to be in the nature of a covalent linkage. The deoxypentose nucleic acids, however, are

found as salts of the strongly basic proteins, the histones. In the case of sperm nuclei they are also found with basic protamines of low molecular weight, which may contain up to 85 per cent of arginine. An unusual characteristic of the deoxypentose nucleoproteins is that they are less soluble in physiological saline solution than in either strong salt solutions or pure water. The insoluble material is highly fibrous and can be collected by winding it around a stirring rod.

When separated from the protein the nucleic acids are sparingly soluble in cold water, insoluble in alcohol, but readily soluble in weak alkali with the formation of the alkali metal salts. They are precipitated from alkaline solutions by hydrochloric acid, but only the pentose nucleic acids are precipitated by acetic acid. In weakly acidic solution the nucleic acids can be precipitated by some proteins, the combination being effectively a nucleoprotein. They form insoluble salts with alkaline earth and heavy metals. When sufficiently purified they do not give the protein color reactions.

**Molecular Size.** Pentose nucleic acid preparations have been demonstrated, by ultracentrifugal measurement of their sedimentation rates, to have molecular weights from a few thousand up to 300,000; however, it is very difficult to avoid degradation in the process of isolation and few samples are available with the higher molecular weights. Similar measurements show molecular weights of deoxypentose nucleic acid to be up to 1,000,000 or 2,000,000, although there is some indication that the particles actually measured may be aggregates of materials of somewhat lower molecular weights. The sodium salt of the deoxypentose nucleic acid can yield a clear solution while warm, but this solidifies to a gelatinous mass upon cooling, which can be again liquefied by warming. When such gels are allowed to flow, or are stirred in a beaker, the gel partially liquefies, and under polarized light the existence of flow birefringence can be seen. This phenomenon is due to the presence of long, slim, fibrous molecules which line up in parallel in the moving solution, but again distribute themselves at random when motion of the solution ceases.

## THE COMPOSITION OF THE NUCLEIC ACIDS

The nucleic acids are composed of nitrogenous heterocyclic bases (the purines and pyrimidines), carbohydrates, and phosphoric acid. The carbohydrates, where identified, have always proved to be the pentoses, D-ribose ( $\text{CHO} \cdot \text{CHOH} \cdot \text{CHOH} \cdot \text{CHOH} \cdot \text{CH}_2\text{OH}$ ), or D-2-deoxyribose ( $\text{CHO} \cdot \text{CH}_2 \cdot \text{CHOH} \cdot \text{CHOH} \cdot \text{CH}_2\text{OH}$ ) and instead of the more general terms pentose and deoxypentose the names *ribose nucleic acid* and *deoxyribose nucleic acid*, frequently abbreviated to *RNA* and *DRNA* or *DNA*, are widely used.

**The Purines and Pyrimidines.** The two purines adenine and guanine and the pyrimidine cytosine are found in both types of nucleic acid. The pyrimidine uracil has been found only in the ribose nucleic acids, and thymine (5-methyl-uracil) is characteristic of deoxyribose nucleic acids. Two other pyrimidines, 5-methyl-cytosine and 5-hydroxymethyl-cytosine, are found only in certain deoxyribose nucleic acids.

Adenine

Guanine

Cytosine

Uracil

Thymine  
(5-methyl-uracil)

With all these structures, tautomerism from lactim to lactam forms is possible, for example:

Tautomeric forms of uracil

**The Nucleotides and Nucleosides.** Each purine or pyrimidine in a nucleic acid is found to be accompanied by one molecule of pentose and one of phosphoric acid. The studies of Levene, Jones, and others demonstrated that hydrolytic cleavage of the nucleic acids could lead to phosphoribosides, or *nucleotides*, of each of the bases. The nucleic acids are polymers of many such nucleotides, and hence the descriptive name *polynucleotides* is a useful one. If further hydrolysis is involved, the phosphoric acid is removed and the ribose derivatives of the bases, the *nucleosides*, are obtained. The relation between nucleosides and nucleotides may be indicated in the diagram and table shown on p. 203.

The nucleic acids used most extensively in the studies of their chemistry have been the ribose nucleic acid from yeast, or *yeast nucleic acid*, and the deoxyribose nucleic acid from thymus gland, or *thymus nucleic acid*. They contain approximately equimolar amounts of each of four

bases. This led to a long prevalent theory that the nucleic acids were tetranucleotides, or at least contained a repeating tetranucleotide unit. However, with the advent of more refined techniques, analyses now indicate that few nucleic acids contain the equimolar quantities of the four bases required by the tetranucleotide theory. The presence of a fifth nucleotide in some deoxyribose nucleic acids also discredits that hypothesis. Present concepts of nucleic acid structure suggest a much greater complexity. These large molecules are still less well understood than are the proteins.

RIBOSE NUCLEIC ACID DERIVATIVES

| Base     | Nucleoside | Nucleotide     |
|----------|------------|----------------|
| Uracil   | Uridine    | Uridylic Acid  |
| Cytosine | Cytidine   | Cytidylic Acid |
| Adenine  | Adenosine  | Adenylic Acid  |
| Guanine  | Guanosine  | Guanylic Acid  |

DEOXYRIBOSE NUCLEIC ACID DERIVATIVES

|         |           |                 |
|---------|-----------|-----------------|
| Thymine | Thymidine | Thymidylic Acid |
|---------|-----------|-----------------|

For the deoxyribose derivatives of the other three bases the prefix "deoxy-" is used with the names above, as in *deoxycytidine*.

**Purine and Pyrimidine Content.** Analyses of the purine and pyrimidine content of various deoxyribose nucleic acids by paper-chromatographic methods have shown variations in the composition of the DNA from various species. Chargaff has shown that though the ratio of total purines to total pyrimidines is usually close to unity, there are types in which the amounts of one purine and one pyrimidine may considerably exceed the amounts of the others. It is of interest that, of the various possible combinations, only two types have been encountered: one in which adenine and thymine predominate, and one in which guanine and cytosine predominate. The former is most frequently found in mammalian tissues, yeast and so forth; the latter is common in bacteria. Some bacteria possess a DNA with nearly equal proportions of the four bases. Where 5-methyl-cytosine is found to be present as a fifth component (in plant, fowl, and mammalian species, including man) it is usually found only in traces, although in the case of the DNA of wheat embryo it amounts to one-eighth of the total base present.

**The Amount of Nucleic Acids in the Cells.**

(a) DEOXYRIBOSE NUCLEIC ACID. The total quantity of deoxyribose nucleic acid per cell is remarkably constant in all the normal somatic tissues within a given species. This amount is not altered by conditions such as starvation or other stress. The amount per haploid (sperm) nu-

cleus is one-half of that for a normal diploid nucleus of the species, and where polyploidy is found the DNA per nucleus is correspondingly increased. There are considerable variations from species to species, fish and birds having generally a smaller amount of DNA per nucleus than mammals (which generally contain in the order of  $6 \times 10^{-9}$  mg. per nucleus). The constancy of the amount of DNA per nucleus and of the composition throughout a species correlates well with the requirement of the genetic theory for a constancy in the character of the chromosome. This is another of the lines of evidence which foster the theory that DNA may be an integral component of the chromosome.

(b) **RIBOSE NUCLEIC ACID.** The ribose nucleic acids of various tissues vary in composition from tissue to tissue, and that of the nucleus differs from that of the cytoplasm. Preparations of RNA satisfactory for analytical studies are few, and no generalizations can be made. The quantity of RNA per cell fluctuates under various conditions. It is greatly influenced by such factors as the nutritional state of the animal and is greater in those cells with higher metabolic activities. For instance, it is high in secretory organs, such as salivary glands and pancreas, where active protein synthesis and secretion are taking place. There is also relatively more RNA in rapidly growing embryonic and tumor tissues. Much circumstantial evidence is available which indicates that there is an increase in quantity and metabolic activity of the RNA just prior to, or associated with, protein synthesis, and the theory that ribose nucleic acid plays a major role in the synthesis of protein has received much support. However, there is yet no concrete evidence of any direct participation of RNA in protein synthesis. Several other suggestions that RNA may be primarily involved in processes such as secretion or energy metabolism have some support. It remains that ribose nucleic acid is a dynamic component of the cell and is certainly associated with active metabolic processes; but a definite assignment of a functional role is not yet possible.

## THE STRUCTURES OF NUCLEOTIDES AND OF POLYNUCLEOTIDES

The pentoses in the nucleosides are attached in a nonreducing N-glycosyl linkage. Note that the formation of a pyrimidine nucleoside requires that the 1 and 2 positions of the pyrimidine be in the lactam form. The positions of attachment, the existence in the furanose form, and the stereochemical configurations have been fully authenticated. In the case of the ribose nucleotides, three isomers are possible, depending upon which one of the hydroxyl groups of the sugar is esterified with the phosphoric acid. In the case of adenylic acid all of the three possible isomers are known (see p. 205).

Two isomers of each of the purine or pyrimidine nucleotides are produced upon alkaline hydrolysis of ribose nucleic acids. These are the 2' and 3' isomers, which were also known as the *a* and *b* isomers during a long uncertainty as to which was which. The chemical properties of the isomeric nucleotides are very similar, but it is possible to separate them by ion-exchange chromatographic techniques. The name *yeast adenylic*

*acid* formerly referred to such a mixture of these isomeric adenylic acids, as obtained from yeast nucleic acid. The discovery that there were not four nucleotides, but four pairs of isomeric nucleotides that could be obtained from ribose nucleic acids, necessitated re-evaluation of many of the structural and metabolic aspects of the polynucleotides.

**One of the isomeric Adenylic Acids**  
(9-β-D-ribofuranosyl-adenine-3'-phosphate)  
(Adenosine-3'-phosphate)

**One of the isomeric Uridylic Acids**  
(1-β-D-ribofuranosyl-uracil-2'-phosphate)  
(Uridine-2'-phosphate)

The third possible isomer of adenylic acid is the one in which the phosphate is attached at the 5' position. This nucleotide, adenosine-5'-phosphate, has long been known to occur in muscle and bears the name *muscle adenylic acid*. It is the adenylic acid from which *adenosinetriphosphate* (ATP) and certain coenzymes are derived, and it thus plays important roles in carbohydrate metabolism, fermentation, and muscular contraction (see Chapter 10).

Enzymatic degradation has provided further information on the nature of the linkages present in RNA. Cleavage of RNA by pancreatic ribonu-

lease liberates the majority of the pyrimidines as the 3'-cytidylic and 3'-uridylic acids. An enzyme-resistant portion remains which is composed chiefly of purine nucleotides. The subsequent action of a phosphodiesterase (prepared from snake venom) leads to the production of all four 5'-mononucleotides, chiefly purine nucleotides but also small amounts of pyrimidine nucleotides. These results suggest that it is the 3' and 5' linkages which predominate in the nucleic acid, despite the fact that it is the 3' and 2' isomers that are produced by the action of alkali.

The production of the mixture of the 2' and 3' isomers upon alkaline hydrolysis of nucleic acids is attributed to the formation of cyclic phosphate esters, such as that depicted here. In this illustration the ribose and its three available hydroxyl groups are presented schematically:

In this triester of phosphoric acid the bond which is *not* involved in the cyclic phosphate is the most labile to alkali and is cleaved first. The cyclic mononucleotides which are thus liberated are then further cleaved by alkali to yield mixtures of the 2' and 3' mononucleotides.

In the deoxyribose nucleic acids the lack of a hydroxyl in the 2' position of the sugar prevents the formation of the cyclic phosphate, as is evident from the formula of thymidine shown on p. 207. The deoxyribose nucleic acids are thus more resistant to depolymerization by alkali; in fact, most methods for separation of the two types of nucleic acid depend upon the difference in their stability in the presence of alkali.

In the ribose nucleic acid the presence of approximately one ionizable hydrogen per phosphate indicates that most of the phosphates are present as diesters. Approximately one quarter of this titratable hydrogen shows a pK of about 6, corresponding to a secondary phosphoryl dissociation, and this indicates that the ribose polynucleotides are not solely diphosphate ester bridges from the 3' to the 5' hydroxyls of adjacent nucleotides. Several other lines of evidence suggest the presence of some monoesterified ribose (i.e., oxidation by periodic acid, production of a dimethyl ribose after methylation), of some triesterified ribose (production of free

ribose after methylation), and of some triesterified phosphoric acid (from titration data). The characterization of a number of di-, tri- and tetranucleotides, which are obtained by partial enzymatic or acid hydrolyses of ribonucleic acids, also reveals that several purine or pyrimidine nucleotides may be adjacent to one another. Sufficient information is not available to plot the sequence of nucleotides in any nucleic acid.

**Thymidine**

(1-β-D-2-deoxyribofuranosyl-thymine)

A formulation such as that shown in Fig. 59 is compatible with the present chemical and enzymatic evidence and indicates the complexity of the structure of the polynucleotides known as *ribose nucleic acids*. This

FIG. 59. FRAGMENT OF A RIBOSE NUCLEIC ACID.

Schematic presentation of the types of linkage involved.

(After Cohn, Doherty, and Volkin: *Phosphorus Metabolism*)  
Vol. 2, Baltimore, Johns Hopkins University Press, 1952.

sketch of the current speculations regarding intermediate linkages represents only a portion of a molecule. A molecular weight of 30,000, for instance, requires nearly 100 nucleotides.

Various enzymatic hydrolyses of the deoxyribose nucleic acids have yielded 3'-nucleotides or 5'-nucleotides. Small amounts of deoxyribose nucleosides bearing two phosphoric acids (in both the 3' and 5' positions) have also been obtained. The nucleotides in DNA must be joined principally by 3', 5' phosphate diester bridges, with possibly some branching through triesterified phosphate.

It should be pointed out that phosphate bridges between the 5' hydroxyls of two nucleotides have not been found, nor have pyrophosphate linkages been implicated. The latter type of linkage is found in those coenzymes which are formed from adenosine-5'-phosphate and various vitamin derivatives. Despite their considerable similarities, there is thus a fundamental difference between nucleoproteins and those enzymes which are complexes of a dinucleotide coenzyme and a protein (see Chapter 12).

## METABOLISM OF NUCLEIC ACIDS

The organism is able to synthesize *de novo* all of its nucleic acids and none of the organic constituents thereof are necessary in the diet. It has therefore been difficult to learn what compounds are utilized in forming the tissue nucleic acids, since classical nutritional and balance studies were able to contribute little. Most of the knowledge of the origin of the nucleic acid components has come from the administration of isotopically labeled compounds and the use of degradative procedures which permit analysis of individual moieties of the products. In this way the principle sources of the individual atoms of the purine ring have been shown to be:

FIG. 60. ORIGIN OF THE ATOMS OF THE PURINE RING.

C—from 1-carbon sources (formate, formaldehyde); N—from  $\text{NH}_3$  (via: aspartate, glutamate, glutamine).

From Brown, Roll, and Weinfeld: *Phosphorus Metabolism*, Vol. 2, Baltimore, Johns Hopkins University Press, 1952.

The 4,5-carbon and 7-nitrogen portion is derived from glycine as a single unit; the 6 carbon arises from carbon dioxide. The 2 and 8 carbons arise

from one-carbon units such as formate or formaldehyde, and folic acid plays a direct role in the incorporation of these one-carbon units. There is no evidence that there is any formation of free purines in the course of biosynthesis in tissues. Rather, the ribose and phosphate are attached to a smaller precursor before the synthesis of the purine ring is fully completed. This has been shown to be true in studies of inosinic acid (hypoxanthine ribotide) biosynthesis in pigeon liver, and the mechanism of synthesis of purine derivatives in this species is probably identical or very similar to such synthesis in the mammal.

In birds and reptiles there is a peculiarity of purine metabolism not observed in mammals. In those species uric acid, instead of urea, is formed directly as the chief catabolic end product of protein nitrogen metabolism.

Among the purines classically associated with purine metabolism, only adenine reaches the nucleic acids in significant amounts when fed to the rat. Adenine is not only incorporated as adenine but is also partially transformed into the guanine of the polynucleotides; and by the use of isotopes it has been demonstrated that the purine ring remains intact during this conversion. Guanine and several other purines are extensively catabolized and, in the rat, do not reach the polynucleotides. Guanine can, however, be readily used by several species of microorganisms, and to a small extent by the mouse, and in most cases it can also be transformed into polynucleotide adenine. A purine which has not been shown to occur in nature, 2,6-diaminopurine (or 2-aminoadenine), can be utilized for the synthesis of polynucleotide purines. In the rat it is converted only into nucleic acid guanine, although in some species it may be converted into both nucleic acid purines.

The nucleoside and nucleotides of adenine may be utilized by the rat, but only if they are administered parenterally, in order to avoid the digestive enzymes of the intestinal tract. Guanylic acid can lead to nucleic acid guanine, although guanosine, like guanine, fails to do so in the rat.

Less is known of the origin of pyrimidines. The 2 carbon can arise from carbon dioxide; and aspartic acid and carbamyl aspartic acid are major precursors of the other carbons of the ring. The pyrimidines uracil and cytosine are not significantly utilized for polynucleotide synthesis, although their nucleosides or nucleotides are very effectively utilized. There is an interconversion of the pyrimidine derivatives, similar to that of the purines, and thus cytidine and cytidylic acid are transformed into ribose nucleic acid uracil and also into deoxyribose nucleic acid cytosine and thymine. The conversion to the latter involves the acquisition of an additional carbon for the 5-methyl group of the thymine. This arises from one-carbon units such as formic acid or the  $\beta$ -carbon of serine; and folic acid is also involved in this reaction. Vitamin B<sub>12</sub> is likewise involved in the formation of thymidine and other deoxyribosides, but its role is not yet adequately defined. It is of interest that a pyrimidine which is found in milk, orotic acid, or 6-carboxyuracil is readily utilized as a precursor of polynucleotide pyrimidines. Its possible significance in infant nutrition is not clarified.

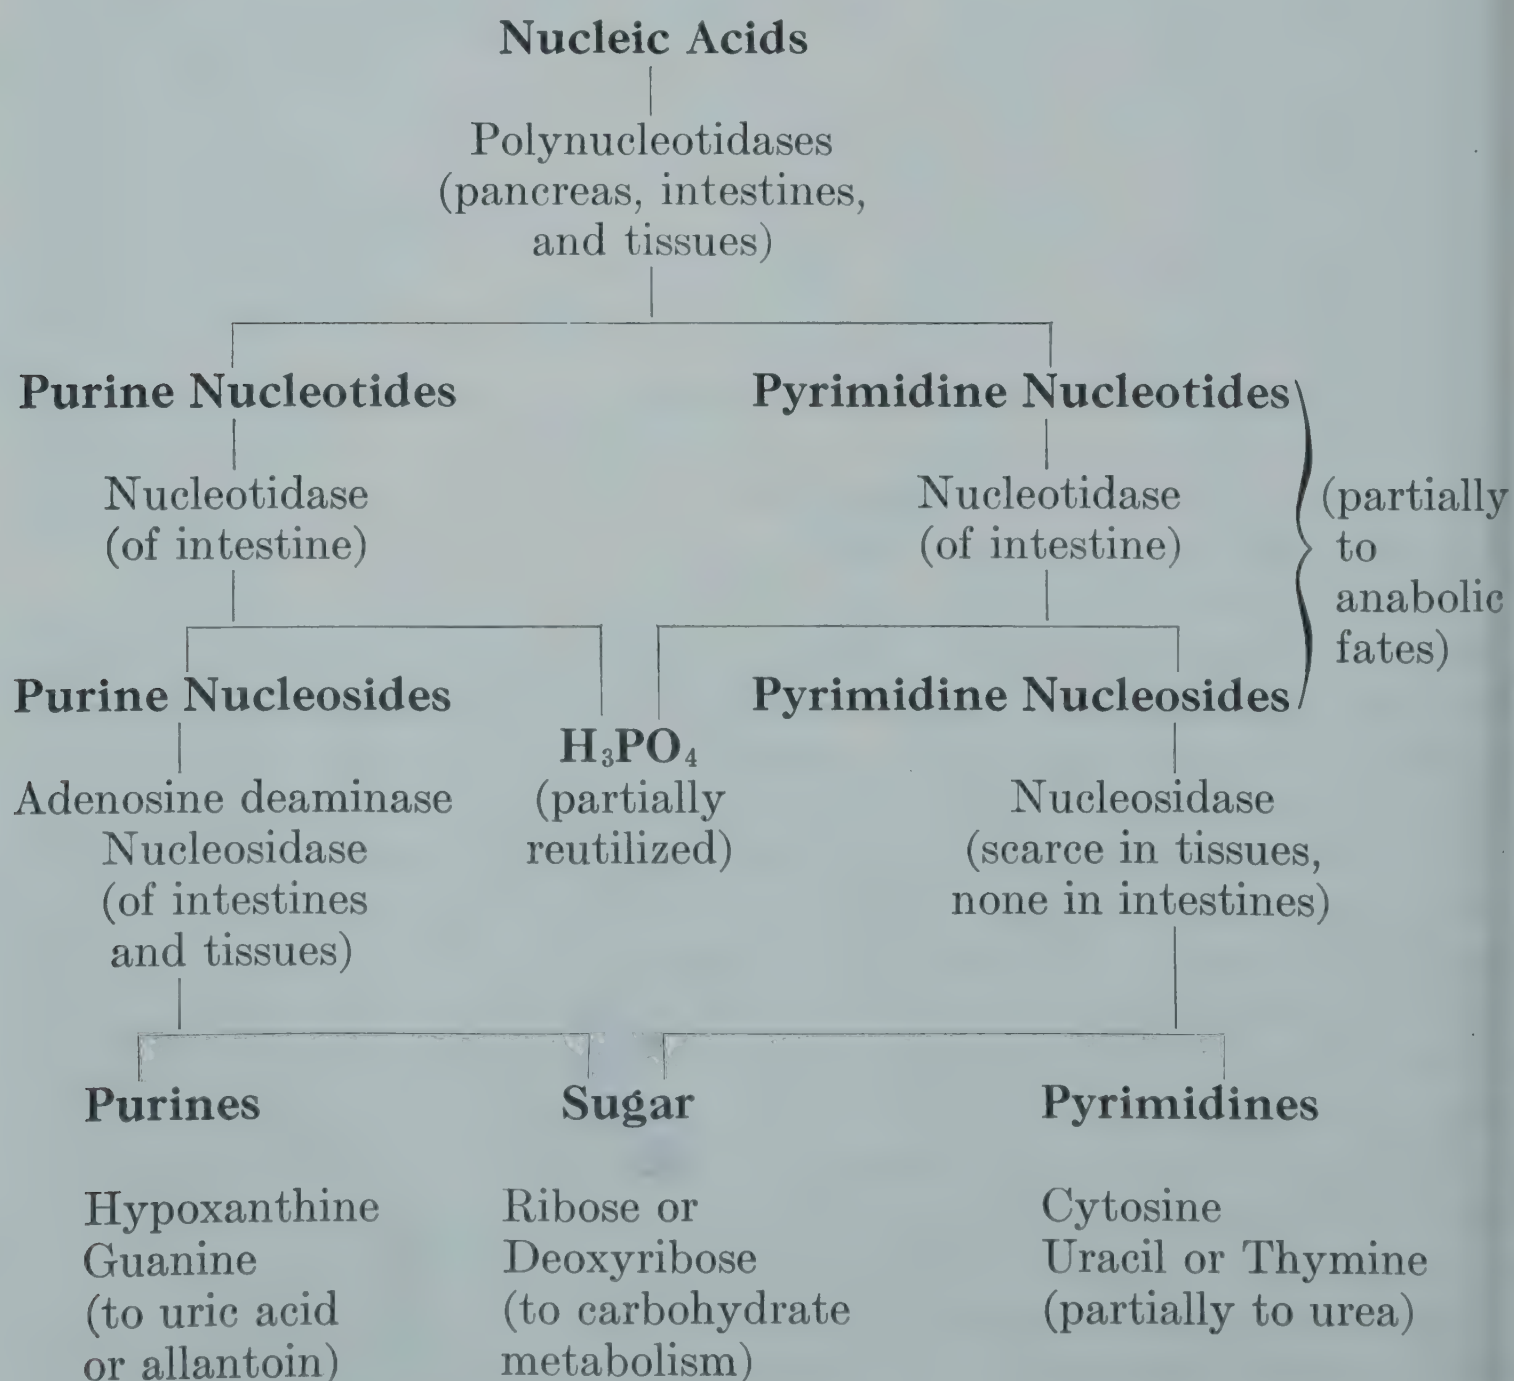

The usual diet contains few sources of individual purines, pyrimidines,

and their nucleosides or nucleotides. Varying amounts, however, of nucleic acids will normally be encountered in the diet, particularly when appreciable quantities of glandular meats are consumed. The feeding of isotopically labeled ribose (yeast) nucleic acid to the rat showed that there was appreciable incorporation of its pyrimidines, but no significant incorporation of its purines, into the tissue nucleic acids. This is in distinct contrast to the fact that when the individual free pyrimidines are present in the diet they are not incorporated. Since adenine and its derivatives can be incorporated it is obvious that the purine moieties of the nucleic acid are catabolized further than the nucleotide or nucleoside stage, and that the catabolic products do not include adenine. On the other hand the pyrimidine moieties which were utilized must have been absorbed before degradation to the free pyrimidines. The fate of the dietary nucleic acid can be correlated with the known fates of the various derivatives and with the known degradative enzymes described below.

### ENZYMATIC BREAKDOWN OF NUCLEIC ACIDS

The following is an outline of the steps and the enzymes involved in the digestion and catabolism of nucleic acids:

The known mammalian nucleosidases do not cleave adenosine but do split inosine (hypoxanthine riboside) and guanosine. The very active

adenosine deaminase does, however, convert adenosine to inosine, and the net result is to lead to purines which are extensively catabolized and not to purines which are utilized for nucleic acid synthesis. The lesser abundance of pyrimidine nucleosidases does not result in the rapid destruction of the ribose derivatives of the pyrimidines.

## CATABOLISM OF PURINES

The purines are readily catabolized to uric acid via a series of deaminations and oxidations as outlined below. Adenosine and its derivatives can reach hypoxanthine through deamination to inosine and cleavage of the inosine to hypoxanthine. If a large amount of adenine is present it can be oxidized directly to 2,8-dioxyadenine, which may cause kidney damage through deposition of crystals of this very insoluble substance in the tubules.

In man and apes, uric acid is the primary end product of purine metabolism, but in other mammals an enzyme, uricase, carries the oxidation

further to the more soluble allantoin. In man intravenously administered uric acid is almost completely excreted as such, and only a small but variable amount is degraded as far as urea. However, orally administered uric acid is extensively degraded to urea, presumably by intestinal bacteria.

In gout the blood uric acid concentrations are increased somewhat above normal, and the ultimate result of the disease is the deposition of tophi of sodium urate in the joints and elsewhere. However the uric acid clearance is usually essentially normal, although it may be decreased where renal impairment has resulted.

In the normal individual there is somewhat less than a gram of uric acid in the blood and fluids, in a volume approximately equal to the extracellular space. The size of this available pool, and its rate of renewal, can be measured by the intravenous injection of a small sample of isotopic uric acid and determination of the course of excretion of the isotope. Benedict and Stettin have shown that in the gouty individual the size of the pool may be increased many fold. Only the outer portions of the tophaceous deposits of urates were found to equilibrate rapidly with administered isotopically labeled uric acid. The etiology of gout is complex but a study making use of isotopic glycine has confirmed the view that increased synthesis of uric acid is a factor.

The administration of ACTH leads to uricaciduria, and in the gouty patient can precipitate an attack of acute gouty arthritis. Increased blood uric acid is one of the outstanding changes observed in eclampsia.

## EXPERIMENTS ON NUCLEOPROTEINS AND THEIR DERIVATIVES

**1. Preparation<sup>1</sup> of Deoxyribosenucleoprotein from Thymus or Spleen.** Fresh tissue is minced and thoroughly washed with physiological saline, containing 0.01 M sodium citrate. The washed tissue is then extracted by stirring with about 10 volumes of 1 M NaCl containing 0.01 M sodium citrate. The suspension is centrifuged at high speed (10,000 to 12,000 r.p.m.) and the supernatant liquid containing the nucleoprotein is removed. This solution is poured into 6 volumes of water (which reduces the NaCl concentration to that of an isotonic solution), and the nucleoprotein precipitates as a fibrous mass. The supernatant liquid is decanted and the nucleoprotein is purified by again dissolving in M NaCl. The solution is centrifuged at high speed to remove any suspended material, and the nucleoprotein is again precipitated by pouring into 6 volumes of water. If the mixture is stirred with a rod having a crook at its end, the fibrous material generally winds around the rod and adheres to it.

**2. Tests on Nucleoprotein.** Try the following tests on a nucleoprotein preparation.

- a. Try the xanthoproteic, Millon, and biuret tests.
- b. Test the solubility in water, 10 per cent NaCl, 10 per cent HCl, dilute KOH, and alcohol.
- c. Test for Phosphorus in Organic Matter. To a small amount of the substance in a crucible add about five times its bulk of fusion mixture (two parts

---

<sup>1</sup> Mirsky and Pollister: *J. Gen. Physiol.*, 30, 117 (1946); Petermann and Lamb: *J. Biol. Chem.*, 176, 685 (1948).

sodium carbonate to one potassium nitrate). Heat carefully until the resulting mixture is colorless. Cool, dissolve the mass in a little warm water, acidify with nitric acid, heat to about 65°C., and add a few ml. of molybdate solution. In the presence of phosphorus a yellow precipitate of ammonium phosphomolybdate is formed.

Instead of acidifying with nitric acid, the aqueous solution may be approximately neutralized with hydrochloric acid, a few ml. of magnesia mixture added, and then excess of ammonium hydroxide solution. A white precipitate of magnesium ammonium phosphate is formed.

d. Dissolve a little of the nucleoprotein in very dilute KOH and then make slightly acid with acetic acid. Explain results.

**3. To Show the Presence of Protein, Carbohydrate, Phosphoric Acid, and Purine Radicals in Nucleoprotein.** Upon complete acid hydrolysis of nucleoprotein, these substances will be liberated, as well as decomposition products of the protein part of the molecule. To show their presence, proceed as follows: Transfer about a gram of nucleoprotein to a small flask and add 50 ml. of 5 per cent  $H_2SO_4$ . Boil for an hour or more to hydrolyze. Maintain the original volume by adding water. The solution becomes brown owing to the formation of melaninlike substances. Cool and filter the acid solution. Apply the following tests to portions of it: (a) the biuret test, (b) the xanthoproteic test, (c) the Molisch test, (d) Benedict's test, and (e) the test for phosphate. (f) Transfer about 25 ml. of the hydrolyzate to a casserole and add ammonia with thorough mixing, a little at a time, until the fluid is nearly neutral. Then make slightly alkaline with dilute ammonia and filter if not clear. Transfer to a beaker and add about 10 ml. of 5 per cent ammoniacal silver nitrate solution. Purine bases will yield a flocculent precipitate of their silver salts. If a precipitate does not appear immediately, examine the solution after it has been allowed to stand undisturbed for some time.

**4. Preparation of Ribose Nucleic Acid from Yeast.** Dilute 50 ml. of 1 per cent NaOH with 250 ml. of water in a casserole and add to this solution 100 g. of compressed yeast cut in small pieces or 30 g. of dry yeast. Heat on the water bath for half an hour with occasional stirring. Remove from the bath and filter at once through a folded filter. To the cooled filtrate add acetic acid until faintly acid to litmus. Filter again. Evaporate the solution to 100 ml. or less, and filter if necessary. Allow to cool to 40°C. or below, then pour with vigorous stirring into 200 ml. of 95 per cent alcohol containing 2 ml. of concentrated HCl. Allow to settle in a tall vessel and decant. Wash twice with 95 per cent alcohol and twice with ether. Transfer to a filter paper. Allow to drain and dry at room temperature.

#### 5. Tests on Nucleic Acid from Yeast.<sup>2</sup>

a. Test the solubility of nucleic acid in cold and hot water, in alcohol, and in dilute acid and alkali. To the solution in alkali add dilute HCl drop by drop until the solution is acid; then add excess of concentrated HCl.

Does nucleic acid coagulate on boiling? Does the solution in hot water gelatinize on cooling?

b. Try the biuret test.

c. Dissolve a little nucleic acid in water with the aid of heat. Test the reaction of different portions of the solution with litmus, alizarin, and Congo red solution.

<sup>2</sup> A satisfactory preparation of yeast nucleic acid may be obtained from Schwarz Laboratories, Inc., Mount Vernon, New York.

d. Boil a small portion of the nucleic acid with about 10 ml. of 10 per cent sulfuric acid for one to two minutes. Divide into three portions.

To one portion apply carbohydrate tests—e.g., the  $\alpha$ -naphthol (Molisch) reaction and Tauber's test. What do these indicate?

To a second portion apply a test for purine bases. Add an excess of ammonia and then a little silver nitrate solution.

To the third portion apply the test for phosphate, adding ammonia in slight excess, then making acid with nitric acid, adding molybdate solution, and warming.

**6. Preparation of Deoxyribose Nucleic Acid.** Freshly excised thymus glands are minced and frozen. The subsequent extractions are carried out as near 0°C. as possible. Homogenize 100 g. of frozen tissue in 200 ml. of cold 0.15 M NaCl solution, which is also 0.01 M in sodium citrate, and centrifuge the mixture at 2000 r.p.m. This operation is repeated three times on the residue and the supernatants are discarded.

The residue is dispersed in about 200 ml. of water<sup>3</sup> in a high-speed blender. With continued stirring sufficient 5 per cent sodium dodecyl sulfate is added to bring the concentration to 0.5 per cent, and sufficient NaCl to make the solution 1 M with respect to it. The mixture is stored at 5°C. overnight and then filtered through a pad of Celite on a Buchner funnel. When clear, the filtrate is poured, with stirring, into two volumes of ethanol. The fibrous precipitate of sodium deoxyribose nucleate is collected and is washed repeatedly with 70 to 95 per cent alcohol.

**7. Tests on Deoxyribosenucleic Acid.** Repeat Exps. 5 (a) through (d) as given under yeast nucleic acid, above. (e) Make a 4 per cent solution of deoxyribosenucleic acid in hot water (0.4 g. to 10 ml.). Allow to cool. What happens? Divide into two portions. To one add a little NaOH solution; to the other add acetic acid. Then neutralize carefully in each case.

Both acetic acid and NaOH decrease the viscosity of the nucleate solution. It may be changed back and forth from the gelatinous to the fluid condition by the alternate addition of acid and alkali.

## 8. Tests on Purine and Pyrimidine Bases and Derivatives.

### (a) XANTHINE.

(1) *Silver Nitrate Reaction.* Dissolve a little xanthine in ammonia and add silver nitrate solution. Examine a little of the precipitate microscopically (see Fig. 61).

(2) *Copper Sulfate Reaction.* Dissolve a little of the substance in dilute alkali, make faintly acid with acetic acid. Heat to boiling. Add 1 ml. of 10 per cent  $\text{CuSO}_4$ , and then a few drops at a time of sodium bisulfite (saturated solution) until the precipitate becomes yellowish. All of the purines give this reaction.

(3) *Nitric Acid Test.* Place a small amount of the substance in a small evaporating dish, add a few drops of concentrated nitric acid, and evaporate to dryness very carefully on a water bath. The yellow residue upon moistening with caustic potash becomes red in color and upon further heating assumes a purplish-red hue. Now add a few drops of water and warm. A yellow solution results which yields a red residue

<sup>3</sup> For best results the solution should be analyzed for nitrogen and the nitrogen concentration adjusted to 0.5 mg. per ml. Marko and Butler: *J. Biol. Chem.*, **190**, 165 (1951).

upon evaporation. Compare with a similar reaction on other purine bases and uric acid. (See the murexide test, p. 796.)

(b) HYPOXANTHINE.

(1) Repeat Exps. 1 and 3 under Xanthine. Examine the crystals of hypoxanthine silver nitrate under the microscope. (See Fig. 62.)

FIG. 61. XANTHINE SILVER NITRATE.

FIG. 62. HYPOXANTHINE SILVER NITRATE.

Drawn from a student preparation by Dr. E. F. Hirsch.

(2) Dissolve a little of the substance in a very small amount of hot 6 per cent nitric acid and allow to cool. Characteristic whetstone crystals of hypoxanthine nitrate should be formed. Examine under the microscope.

(c) ADENINE.

(1) Dissolve a little adenine in hot water and add a few drops of picric acid. Examine the pale yellow clusters of needles under the microscope.

(2) Repeat Exp. 3 under Xanthine.

## (d) GUANINE.

(1) Dissolve a little of the substance in 20 to 25 times its weight of boiling 5 per cent alcohol. Allow to cool and examine the crystals under the microscope.

(2) Dissolve a little guanine in 20 to 25 times its weight of boiling 5 per cent hydrochloric acid. Allow to cool, and examine the crystals.

(3) Perform Exp. 3 under Xanthine.

(e) URIC ACID. On a small amount of uric acid, try Test 3 as given under Xanthine. This test on uric acid is called the murexide test. For other tests on uric acid see Chapter 28, Urine.

(f) REACTIONS FOR URACIL, CYTOSINE, AND THYMINE. Treat an aqueous solution of each pyrimidine with an excess of bromine. Remove the excess by boiling the solution. Add barium hydroxide in excess. A purple color indicates cytosine or uracil and is due to the purple barium salt of dialuric acid.

Reflux for a few minutes and distill. If thymine is present,  $\text{CO}_2$ , urea, and acetol ( $\text{CH}_3\text{COCH}_2\text{OH}$ ) are formed, and the acetol distills over. Make strongly alkaline with  $\text{NaOH}$ . Add several drops of *o*-amino-benzaldehyde.<sup>4</sup> Evaporate over a flame to half the volume. Cool. Make distinctly acid with  $\text{HCl}$  and then alkaline with  $\text{NaHCO}_3$ . Filter. A blue fluorescence of 3-oxyquinaldine indicates acetol and the original presence of thymine.

(g) ULTRAVIOLET ABSORPTION SPECTRA. The availability of convenient and relatively inexpensive ultraviolet spectrometers has made it possible to make most of the quantitative and qualitative measurements of the individual purines and pyrimidines through their strong and characteristic ultraviolet absorption spectra. See also p. 283.

**9. Methods for the Separation of Purines and Pyrimidines.** Procedures which involve fractional crystallization for the separation of purines and pyrimidines have been largely superseded by the techniques of ion-exchange separation or paper chromatography.

(a) CRYSTALLIZATION OF DERIVATIVES OF GUANINE AND ADENINE FROM NUCLEIC ACID. Place 5 g. of yeast nucleic acid in a 200-ml. Erlenmeyer flask, add 100 ml. of boiling-hot 5 per cent sulfuric acid and heat carefully over a small flame to bring the nucleic acid into solution. During this heating, which lasts only a minute, the contents of the flask should be kept constantly in motion to avoid charring the undissolved nucleic acid. Close the flask with a cork bored with one hole into which is inserted a condensing tube. Immerse in a boiling water bath and heat for about an hour. Disconnect the flask and while its contents are still hot add concentrated ammonia a drop at a time until the fluid is slightly alkaline, and then add 5 ml. of concentrated ammonia in excess. Guanine is thus precipitated in granular form, while all of the other products including phosphoric acid and adenine remain in the ammoniacal solution.

After several hours, collect the precipitated guanine and wash it with 1 per cent ammonia. Dissolve in as small an amount of 20 per cent sulfuric acid as possible, add a little charcoal, and boil. Filter, heat to boiling, and precipitate with an excess of ammonia. Filter, dry the precipitate at  $40^\circ\text{C}$ ., and dissolve it in about 20 parts of boiling 5 per cent hydrochloric acid. As the solution cools, guanine hydrochloride separates as needle-shaped crystals.

<sup>4</sup> Mix 3 g. of crystalline *o*-nitrobenzaldehyde with 50 g. of crystalline ferrous sulfate. Add 75 ml. of concentrated ammonia. Heat on a steam bath for one hour. Distill off the *o*-amino-benzaldehyde with steam. The mixture before distillation will keep for two weeks.

Combine the ammoniacal filtrates obtained in the isolation and purification of guanine. Filter if necessary. The ammonia is then boiled off and an excess of picric acid added. The yellow precipitate of adenine picrate is collected and dried. The adenine picrate can be recrystallized from 25 per cent acetic acid. Adenine can be recovered from the picrate by acidification with HCl and long extraction with ether, or by the use of an ion-exchange resin which will take up the picric acid.

(b) SEPARATION OF PURINES BY ION-EXCHANGE CHROMATOGRAPHY. Place a loose pad of glass wool in the bottom of a 50 ml. burette. Add about 25 ml. of water and then sufficient suspension<sup>5</sup> of Dowex 50 (hydrogen ion form) to make a resin bed 2 cm. high. Wash the resin into place by filling the buret to the top with water and allowing it to drain. Use a long rod to push another loose pad of glass wool down to the top of the resin bed. The rate of flow should be about 7 or 8 ml. per minute when the buret is full, and 2 or 3 ml. per minute for the last few ml. in the buret. The stopcock should always be closed just before the liquid level reaches the top of the resin bed. Arrange a series of eight numbered tubes for collection of fractions from the column.

Charge the column by pouring in a solution of 0.5 mg. of hypoxanthine and 0.5 mg. of adenine in 50 ml. of 0.1 N HCl and allowing it to drain. Wash the column with a few ml. of water and combine the effluents as Fraction 1. Elute the purines from the column with five consecutive 25-ml. portions of 2 N HCl. Then elute with two 25-ml. portions of 4 N HCl for Fractions 7 and 8.

Test for purines in the eluates by reduction, diazotization of the products of reduction, and coupling with the Bratton-Marshall reagent, as follows. Place about 5 ml. of each fraction in clean test tubes. To equalize the acid concentrations add 2 ml. of 6 N HCl to Fraction 1, and dilute Fractions 7 and 8 with equal volumes of water. As controls use 0.025 mg. of hypoxanthine and 0.025 mg. of adenine, each in 2 N HCl, and a 2 N HCl blank. 1) To each tube add a pinch of Zn dust the size of a match head and place immediately in a boiling water bath for 5 to 7 minutes. 2) Cool the tubes by transferring to a beaker of tap water and filter each. 3) To each filtrate add 1 ml. of 0.3 per cent sodium nitrite solution. 4) After 10 minutes add 1.5 ml. of 0.5 per cent ammonium sulfamate solution. 5) Add to each 1 ml. of 0.2 per cent N-(1-naphthyl)ethylenediamine solution.<sup>6</sup> The bulk of the hypoxanthine (which leads to a pink-purple color) should be in Fractions 2 and 3. A little adenine (which yields an orange-pink) will appear in Fraction 6, but most of it in Fraction 7. The pattern of elution from the column depends to a considerable extent upon the length and compactness of the resin bed.

With larger columns operated more slowly, it is possible to effect more complete separation of complex mixtures of purine and pyrimidine derivatives and of isomeric nucleotides, than by the foregoing method. For a discussion of ion-exchange resins and column chromatography, see Chapter 1.

(c) PAPER CHROMATOGRAPHIC SEPARATIONS OF PURINE AND PYRIMIDINE DERIVATIVES. Preparation of the paper: On a sheet of filter paper 17 by 26 cm. (Schleicher and Schull No. 597) draw a light pencil line 2 cm. from one of the long edges. Place single drops of the compounds to be studied at intervals of 2 or 3 cm.

<sup>5</sup> Dowex 50 (H<sup>+</sup>) 200-400 mesh, is prepared by suspension in 5 volumes of water and removal, by decantation, of any very fine material which settles slowly. The resin is then washed by heating 1 hour in 2 N NaOH on a steam bath; then with 4 or 5 changes of 4N HCl (or in a column until free of material absorbing in the ultraviolet). It is then washed by repeated changes of water until the effluent is nearly neutral. Store under 2 volumes of distilled water. When well shaken, 6 ml. of the suspension will furnish 2 ml. of resin.

<sup>6</sup> This solution is stored in a dark bottle, and all solutions for the Bratton-Marshall test should be prepared fresh each week.

along this line and allow them to dry thoroughly (or dry under an infrared lamp). If more than one drop proves to be needed, the first must be thoroughly dry before the second is added. Each spot should contain about 25  $\mu\text{g}$ . Roll the paper and staple it to form a cylinder 17 cm. high (do not overlap the edges of the paper but allow the staples to serve as links between the edges).

Stand the cylinder of paper in a 10 cm. petri dish filled to a depth of about 5 mm. with the appropriate solvent. Cover with a bell or battery jar.<sup>7</sup> When the solvent has migrated nearly to the top edge of the paper, flatten the paper and dry, in a well-ventilated oven if possible.

Inspect the papers under a low-intensity ultraviolet lamp<sup>8</sup> and outline in pencil those dark areas where the compounds absorb or quench the fluorescence of the paper. The distance the compound moves, expressed as a fraction of the distance between the starting point and the solvent front, is known as the  $R_F$  value of the compound. For a discussion of paper chromatography, see Chapter 1.

1) Spot adenine, guanine, hypoxanthine, and mixtures of adenine and guanine and of adenine and hypoxanthine. Develop with *n*-butanol saturated with water, with a small container containing a few ml. of conc.  $\text{NH}_4\text{OH}$  also placed under the jar. Allow about 3 to 4 hours for development.

2) Spot the same compounds and develop 3 hours in 70 per cent ethanol. This solvent is rapid, but the spots are less discrete. Adenine and hypoxanthine can be differentiated from guanine, but not from each other.

3) Spot guanine, adenine, cytosine, uracil, thymine, and mixtures of guanine and uracil and of adenine and thymine. Develop in isopropanol-2 N  $\text{HCl}$ ,<sup>9</sup> for about 16 hours. This solvent moves slowly but does permit differentiation of all these five bases.

### Milk

The first food naturally taken by the newborn baby or the young of any mammalian species is *colostrum*. This is the secretion of the mammary glands during the earliest phases of lactation. Although it may appear before parturition, it is characteristic of the second or third day *post partum* of the human mother, and is secreted in a total amount of about 100 ml. This early secretion is more viscous, richer in protein and salts, and poorer in sugar and fat than milk. The color of human colostrum is lemon yellow while that of cattle is reddish yellow. Bovine colostrum, examined just after calving, usually contains vitamin B<sub>12</sub> in concentrations significantly higher than the 7  $\mu$ g. per liter average found in mature milk.<sup>1</sup> Colostrum, unlike mature milk, is heat-coagulable, since it contains high concentrations of *globulins*, sometimes exceeding 10 per cent in cattle. Among these globulins have been identified many immune globulins.

It has been recognized for more than half a century that newborn mammals acquire immunity to certain infections by ingestion of colostrum. This mechanism appears to be more important in calves than in babies. Immune globulins are absent from the blood of newborn calves, but appear three hours after colostrum is fed. This ability to absorb significant amounts of intact protein appears in the newborn of several species, but is limited to their first 24 to 48 hours. There is evidence<sup>2</sup> that the absorption of immune globulins is effected by the intestinal lymphatics rather than by the portal system. The presence of *trypsin inhibitor* in colostrum<sup>3</sup> may aid this temporary process of passive alimentary immunization by delaying the digestive hydrolysis of protein.

In cattle, *precolostrum* may be expressed from the udder at about half-term. The globulin content is high, but the normal constituents of milk are deficient. The presence of precolostrum before lactation starts and its dilution with milk as lactation begins explain the composition of colostrum and the short duration of its production at the start of lactation. An antibody (agglutinin for *Brucella abortus*) has been fractionated from the globulins of precolostrum.<sup>4</sup>

**Mature Milk.** In human lactation, the secretion of colostrum does not continue beyond the fifth day after childbirth. There is a transitional

period of about five more days, during which the components gradually change their proportions to those of mature milk. The fat content of human milk increases during the transitional period and continues to rise for the first two weeks, with no consistent variation after the third week. Increase in lactose content continues for several weeks after the establishment of mature milk flow.

COMPOSITION OF MATURE MILK

\* Summarized from Macy, Kelley, and Sloan, *The Composition of Milks* (Bull. Nat. Research Council, #119), Washington, D.C., 1953.

In the dairy cow, the change from colostrum to mature milk is a continuous process, taking from 5 to 12 days. The composition of mature milk is subject to considerable variation, depending upon the breed and the state of nutrition of the dairy animal, the duration of lactation, and the climate. Therefore, the accompanying table and similar tabulations purporting to represent the composition of milk must be recognized as simplified collections of averages, deviations from which are to be expected in the analysis of any particular sample of milk. The extent of some of these deviations will be indicated in following sections. For much more detailed tables, including many constituents not considered here, consult the monograph of Macy, Kelley, and Sloan, from which the figures of the table above were summarized. The customary pooling of market milk tends to minimize variations in composition. In the process of pooling, the fat content is usually standardized. Since milk is an important article of commerce, and since its nutritive value is of importance to the public health, standards of composition have been enacted into law. Legal definitions of milk vary in different jurisdictions, but many are consistent with the following:

Milk is hereby defined to be the lacteal secretion, practically free from colostrum, obtained by the complete milking of one or more healthy cows, which contains not less than  $8\frac{1}{4}$  per cent milk solids—not fat, and not less than  $3\frac{1}{4}$  per cent milk fat. (*Milk Ordinance and Code—1953*, Recommendations of the Public Health Service.)

By this and most public regulations in the United States, the designation “milk” is limited to the milk of the cow, with the legal implication that

the milks of other species may not be sold simply as "milk." Furthermore, in many jurisdictions, milk of other species is not subject to the requirements of quality and cleanliness imposed by law.

**Milk Sugar.** The only carbohydrate present in nutritionally significant amount in milk is *lactose*, a disaccharide consisting of one glucose unit and one galactose unit with the glycoside link between the carbon 4 of glucose and the carbon 1 of galactose. This glycoside link possesses the beta configuration, so that the full chemical name of lactose is D-glucopyranose-4-( $\beta$ -D-galactopyranoside). Lactose is a reducing sugar and exhibits mutarotation, since carbon 1 of the glucose portion is free. Like other reducing disaccharides, lactose reduces acid  $\text{Cu}^{++}$  solutions more slowly than do monosaccharides, and hence can be distinguished from them by the use of Barfoed's reagent. Lactose forms a specific phenyl-osazone, yields a positive mucic acid test, and is not fermented by the ordinary commercial strains of yeast.

Lactose is formed by the mammary gland from glucose or glycogen.<sup>5</sup> The lactose content of milk is not notably altered by changes in the maternal diet or level of blood sugar. Lactose can frequently be detected in specimens of human urine collected *post partum* or during lactation.

Lactose is converted to lactic acid in the ordinary souring of milk, which is brought about by enzymes of *Streptococcus lactis* and numerous other microorganisms. The first step in this conversion is the hydrolysis of lactose by lactase in the surface of the bacterial cell.<sup>6</sup> The glucose is converted to glucose-6-phosphate by the usual steps. Galactose is phosphorylated by ATP to  $\alpha$ -galactose-1-phosphate in the presence of galactokinase. In the presence of uridine diphosphoglucose,  $\alpha$ -galactose-1-phosphate is converted to  $\alpha$ -glucose-1-phosphate, which is converted to glucose-6-phosphate by steps which, together with subsequent glycolytic steps, are identical in lactic acid bacteria with those in muscle (see Chapter 10).<sup>7</sup>

The percentage of lactose varies significantly in the milks of different species. Human milk has a higher lactose content than that of dairy animals. The mean value in statistically adequate studies is close to 7 g. per 100 ml. human milk, with standard deviations less than 0.5 g. The mean for cattle and goats is slightly less than 5 g. lactose per 100 ml. milk, with somewhat larger variations. When babies are reared on dairy milk, it is customary to add carbohydrate in the form of lactose, sucrose, glucose, or partially hydrolyzed starch (maltose and dextrans).

Lactose is present in no other foodstuff than milk, except of course foodstuffs to which milk or lactose from milk may have been added. Compared with the other common sugars, lactose is less soluble and less sweet. The lack of sweetness is considered to be advantageous in the feeding of infants and invalids, since there is less tendency to cloy the appetite. Nutritional-balance studies<sup>8</sup> with a small group of children have indicated

that calcium retention is greater on a diet containing 36 g. of lactose per day than on one otherwise equivalent but with no lactose.

**Milk Lipides.** Fats occur in milk in the form of suspended globules, of a size easily observed with the low-power microscope. The size of the fat globules in a given specimen of milk is somewhat variable, the largest globules being about seven times the diameter of the smallest. Some variations in average size of fat globules occur in the different breeds of dairy cattle. It is apparent from the large size of the globules of fat in milk that such a suspension of fat in an aqueous system would not be indefinitely stable.

A large proportion of the fat of cow's milk rises spontaneously to the top of the container upon standing, and may be skimmed off as cream. The separation of cream is sharper and more rapid if the milk is first diluted. The centrifugal separator effects a prompt separation of cream without dilution. A sharp cream line is seldom observed when human or goat's milk is allowed to stand, but the cream can be separated by dilution and standing or by centrifugation. This difference in cream-rising, in part the result of larger fat globules in cow's milk, can be altered by *homogenization*, which is the mechanical reduction of the size of fat globules.

The mean values for fat in human, cow's, and goat's milk (see p. 220) are not far apart. In contrast to this consistency of average values in the three species, individuals vary widely in the fat content of milk, and among cattle and goats there are distinct differences according to breed. The milk of Holstein cattle tends to run below the mean value of 3.8 per cent, whereas good specimens of Jersey cows almost consistently give milk exceeding 5 per cent in fat content. The records for fat production, however, are, and long have been, held by Holsteins, since they make up for lower fat percentage by higher volume production of milk. Low fat values around 1 per cent and high values around 9 per cent have been occasionally recorded on authentic specimens of human, cow's, and goat's milk even when proper precautions have been taken to avoid sampling errors.

The fat content of cream varies according to the method of separation and is usually less than 35 per cent. Butter is a still more concentrated form of milk fat, containing more than 80 per cent. The Babcock test for fat in milk was introduced in 1890 as a practical method for routine use in dairies and creameries. High analytical accuracy was not claimed. In practice, the Babcock test has been found to give results only slightly (0.05 to 0.07 per cent) higher than the standard Roesse-Gottlieb ether-extraction method, or its mechanized equivalent, the Mojonnier method. The modification of the Babcock test described in the experimental section of this chapter is not official, and would not be acceptable in establishing butterfat records or in court actions. In such situations the analyst should familiarize himself with the regulations governing butterfat analyses in his particular state or territory.

The triglycerides which compose milk fat contain a complex mixture of fatty acids, with oleic and palmitic acids quantitatively predominant. The fat of human milk is characterized by a somewhat higher proportion

of oleic acid, and a relative deficiency of short-chain fatty acids (butyric, caproic, caprylic, and capric) as compared to goat's or cow's milk. Comparing the latter two species, cow's-milk fat has much more stearic acid, somewhat more butyric acid, and notably less caproic, caprylic, and capric acids than goat's milk. These differences in fatty acid distribution are probably of little nutritional significance, but become apparent when one compares the butyric odor of rancid cow butter with its goat counterpart. Of greater significance are certain fatty acids with more than one double bond. Rats develop dermatitis when fed an otherwise adequate diet deficient in such multiply unsaturated fatty acids. Hansen and Burr<sup>9</sup> list linoleic acid, linolenic acid, and arachidonic acid as normal dietary components which in very small amounts will relieve this deficiency. The milks of all three species discussed contain arachidonic acid, and the concentration in goat's and cow's milk is somewhat higher than in human milk. The presence of linoleic acid in milk has been verified.<sup>10</sup>

Cholesterol is present in small amounts in milk. The mean value for cow's milk is 11 mg. per 100 ml.<sup>11</sup> Both fatty acids and cholesterol are synthesized in the lactating mammary gland, as demonstrated by the rapid incorporation into these milk lipides of injected carboxy-C<sup>14</sup> acetate, both in the intact lactating goat<sup>12</sup> and in the perfused isolated udder of the cow.<sup>13</sup>

**Milk Proteins.** Human milk is notably low in protein content, with a mean concentration of 1.2 g. per 100 ml. and rare variations below 1 or above 2 g. The mean values for cow's and goat's milk are 3.3 and 3.4 g. per 100 ml., most analyses falling within the limits of 2 and 5 g. In the preparation of formulas for feeding young infants, dilution of dairy milk is a customary but not universal practice. Although such dilution, together with the addition of carbohydrate, yields a mixture more closely resembling human milk, the emphasis in present-day infant feeding is upon meeting the nutritional needs of the infant rather than upon close imitation of the composition of human milk.

The chief and characteristic protein of milk is *casein*, a complex of phosphoproteins which makes up a third of the protein of human milk, three-fourths of the protein of goat's milk, and a little over five-sixths of the protein of cow's milk. Casein is definitely not a single molecular species, since three electrophoretic peaks have been distinguished (see p. 7). Fresh milk, at its pH of  $6.6 \pm 0.2$ , has as its chief colloidal component a complex of calcium caseinate and phosphate.<sup>14</sup> If the milk is brought by natural souring or by cautious acidification to pH 4.55, the isoelectric point of casein, this complex is broken up and casein is precipitated. The product of such a precipitation may be designated *isoelectric casein*. Casein can also be precipitated by the action of certain proteolytic enzymes, the best known of which is *rennin* (*rennet* to cheese-makers)

<sup>14</sup> Leviton and Haller: *J. Phys. & Colloid Chem.*, **51**, 460 (1947).

obtained from the fourth stomach (*abomasum*) of nursing calves. Rennin does not occur in the human being, but other enzymes, in particular pepsin and chymotrypsin, carry on the same function. Crystallized rennin has been shown to be a proteolytic enzyme which, in causing milk to curdle, hydrolyzes one peptide bond per 10,000 in casein.<sup>15</sup> The precipitate resulting from the coagulation of milk by proteolytic enzymes is therefore not identical with isoelectric casein, but has been subjected to a mild degree of proteolysis. This product is called *paracasein*, and at pH values above the isoelectric point, is precipitated as *calcium paracaseinate*. Further proteolysis of casein yields the usual intermediate products of protein hydrolysis, except that *phosphopeptones* containing phosphoserine have been isolated from tryptic digests of casein. The caseins of milks of different species are not identical in composition.

Except for some cottage cheese (Dutch cheese or *schmierkäse*), which is usually crude isoelectric casein, the varieties of cheese on the American market are made from the calcium paracaseinate obtained by rennin coagulation of milk. *Cheddar* is obtained by rennin coagulation of milk, preferably pasteurized while fresh and then slightly soured by a starter of lactic acid bacteria. Later processes include cutting the curd, heating to about 40° C., straining, and *cheddaring*, which consists of matting the cheese together by piling, cutting, and repiling. During the final curing process, *Lactobacillus casei* overgrows other organisms and produces the characteristic flavor. *Swiss cheese* is started in a similar manner, but is cultured with *Propionibacterium shermanii* to produce the "eyes" and the sweetness. There is no cheddaring process, but the curd is cut and cooked firm. Curing takes three to six months, during which time bacteriological errors may occasionally produce such anomalies as "blind" cheeses, "stinkers," and "blowers." Although in France *Roquefort* is often made from ewe's milk, American blue cheeses are made from cow's milk, and are started like cheddar. The cut curd is drained, placed in small perforated forms, and sprinkled with *Penicillium roqueforti*. Further ripening and proper mold-mottling requires carefully controlled curing for six to nine months. The ripening of *Limburger* depends upon *Bacterium linens* and other naturally occurring bacteria of the milk acting upon a rennin curd produced from fresh milk without a starter, and takes about two months. Yeasts growing on the cheese surface provide essential nutrients for *B. linens*.<sup>16</sup> *Camembert* is the product of natural bacteria working inside the cheese while the mold *Penicillium camemberti* grows on the outside.

Casein originates in the lactating mammary gland. Certain of its component amino acids have been shown by isotopic identification to be taken up from the free amino acids of the blood,<sup>17</sup> and not from plasma proteins. The phosphorus of casein has similarly been shown to be derived from the inorganic phosphate of the blood. In the goat, about two hours are required for the transport of these substances from circulating blood to the casein of the milk.

<sup>15</sup> Nitschman and Varin: *Helv. chim. acta*, **34**, 1421 (1951).

<sup>16</sup> Purko, Nelson, and Wood: *J. Dairy Sci.*, **34**, 639 (1951).

<sup>17</sup> Barry: *J. Biol. Chem.*, **195**, 795 (1952).

Proteins other than casein constitute more than half of the proteins of human milk, and an appreciable fraction of the proteins of dairy milk. True globulins have already been mentioned in connection with colostrum. After the removal of casein from cow's milk by isoelectric precipitation, the remaining whey is found to contain 0.6 to 0.7 per cent protein, of which roughly one-fourth is globulin, as shown by its being precipitated when the whey is saturated with magnesium sulfate at pH 7; one-half is albumin, which is not so precipitated but is heat coagulable; and the remaining fourth is proteose, which is not heat-coagulable. From the "albumin" fraction has been crystallized a  $\beta$ -lactoglobulin which is probably identical with other preparations described as lactalbumins. The amino acid composition of  $\beta$ -lactoglobulin is quite different from that of any plasma protein, but the immune globulins of colostrum are similar in composition to their plasma counterparts.

Among the proteins of milk are included numerous *enzymes*. The pattern of enzymes is quite different in milks of different species. Aldolase and xanthine oxidase (Schardinger enzyme) are present in cow's milk but not in human milk. Catalase and peroxidase are present in raw milks. Human milk, particularly rich in amylase, promptly liquefies starch paste. The lipase of human or bovine milk brings about a slow liberation of free fatty acids from milk fat. Cow's milk collected in mid-lactation contains from 80 to 120 King-Armstrong units of alkaline phosphatase (phosphomonoesterase) per 100 ml., compared with a range of 0.7 to 16.2 units in human milk and a mean of 4.8 units (Kon and Mawson). The phosphatase content of cow's milk has been made the basis of tests for adequate pasteurization, since the enzyme is readily destroyed by heating.

ESSENTIAL AMINO ACIDS IN WHOLE MILK PROTEINS

\* These representative data are derived largely from Block and Bolling, *The Amino Acid Composition of Proteins and Foods*, Charles C Thomas, Springfield, Ill., 1951. The N = 16 convention is used in dietary calculations, although for milk proteins (largely casein) N = 15.7 (i.e. protein = N  $\times$  6.38) is more accurate. For additional data on individual milk proteins see table on p. 122.

The *biological value* of a protein food is defined as the ratio (expressed as percentage) of the food nitrogen retained to that absorbed (see p. 1047). It is usually determined by feeding experiments on growing rats. A high value indicates adequacy in content and availability of so-called essential

amino acids. The biological values of human and cow's milk are identical within limits of experimental error, the numerical range being 85-90. This high biological value is confirmed by direct analysis of milk proteins for essential amino acids. The *essential amino acid index* of cow's-milk protein based on the relationship between its essential amino acid content and that of whole-egg protein (assumed to equal 100) is 90; the corresponding index for human-milk protein is 93. These index values are closely correlated with the biological values.<sup>18</sup> The table on p. 225 demonstrates the adequacy of whole milk in those amino acids generally regarded as indispensable in the human diet. This question is more fully discussed in Chapter 33.

**Inorganic Milk Components.** The crude figures for ash in the table on p. 220 indicate that the concentration of total minerals is more than three times as great in the milk of dairy animals as in human milk. The important bone-mineral elements, calcium and phosphorus, are both present in milk in nutritionally significant amounts and in a ratio suitable for effective absorption and utilization.

*Calcium* is present in human milk in concentrations which vary through a range of 10 mg. per 100 ml. on either side of a mean of 30 mg. Cow's or goat's milk averages close to 130 mg. per 100 ml. The calcium of milk is present in part as calcium ion, and in part bound as a colloidal complex with protein and phosphate.

*Phosphorus* has a mean value of 13 mg. per 100 ml. in human milk, with a standard deviation of 1.9 mg. (Kon and Mawson), but is found in amounts averaging 100 mg. per 100 ml. of dairy milk, 70 to 80 per cent of the total phosphorus being in the form of inorganic phosphate. The remainder includes phosphoprotein, phospholipide, and ester phosphorus. A variable portion of the inorganic phosphate is separable by ultrafiltration as a part of the colloidal calcium caseinate-phosphate complex.

During that period of early life when milk is the only food taken, *potassium* is equal in importance to the bone minerals. At all ages, the body contains more potassium than sodium, but the difference is greater with growth. Human milk contains approximately 11 milliequivalents of potassium and 5 milliequivalents of sodium per liter; this ratio seems to be optimal for the growth of the infant. Dairy milk contains these ions in comparable ratio, but in concentrations about three times higher. *Chloride* ion is present in highly variable amounts. *Magnesium* averages 4 mg. per 100 ml. of human milk, and three to four times this concentration in dairy milk. The *sulfur* of milk is almost entirely in the form of the sulfur-containing amino acids of milk proteins, and averages 30 mg. per 100 ml. of cow's milk, and about half this value in human or goat's milk.

In addition to those mentioned above, a number of other elements are present in small and variable amounts. Milk is notoriously deficient in *iron*. Analytical figures from different laboratories are widely divergent, but for cow's milk, a concentration of 0.32 mg. per kg. is representative.<sup>19</sup> The iron content of milks of other species is comparable. The full-term human infant born of an adequately nourished mother has a store of iron

<sup>18</sup> Oser: *J. Am. Dietet. Assoc.*, **27**, 396 (1951).

<sup>19</sup> Johnston: *Food Res.*, **9**, 212 (1944); Johnston, Gellman, and Strom: *J. Biol. Chem.*, **175**, 343 (1948).

for about six months of growth on a milk diet without developing an iron-deficiency anemia. After six months, supplementary iron-containing foods should be introduced into the diet. *Copper* occurs in raw cow's milk in about the same concentration as iron. Higher concentrations may result from contact with copper or brass during pasteurization or other processing. Copper in excess of 0.5 mg. per kg. produces a tallowy flavor and loss of ascorbic acid in milk. Average values for other trace elements in cow's milk are given by Archibald<sup>20</sup> as follows:

|            |      |     |     |       |
|------------|------|-----|-----|-------|
| Manganese  | 22   | μg. | per | liter |
| Zinc       | 3900 | "   | "   | "     |
| Cobalt     | 0.6  | "   | "   | "     |
| Molybdenum | 73   | "   | "   | "     |
| Nickel     | none |     |     |       |

The presence of iodide has been demonstrated in the milk of women and of animals. Electrophoretic evidence has indicated that milk contains an iodinated protein.<sup>20a</sup>

**Vitamins in Milk.** Milk and milk products are outstanding sources of certain vitamins, and less reliable for the supply of others.

*Thiamine* is present in human milk in amounts which roughly reflect the vitamin B<sub>1</sub> intake of the mother. At moderate levels of intake, about 10 per cent of ingested thiamine is secreted into the milk (Kon and Mawson). The concentration of total thiamine (in the milk of mothers whose intake is between 1.5 and 2 mg.) usually lies between 14 and 19 μg. per 100 ml. In early lactation, from 50 to 90 per cent of the thiamine of human milk is in a combined form which is not reactive in the thiochrome test, but becomes reactive after enzymic hydrolysis with *takadiastase*, which contains numerous enzymes including phosphatases and proteases. In general, high content of combined thiamine is associated with low values of milk phosphatase. Both free and combined thiamine are measurable by bioassay. The proportion of free thiamine increases with the duration of human lactation.

The milk of goats and cattle contains somewhat more than twice the concentration of thiamine in human milk. About half is in the form of free thiamine in cow's milk, and about one sixth in goat's milk. Thiamine pyrophosphate added to cow's milk is promptly hydrolyzed in the presence of the enzymes pyrophosphatase and phosphatase. A portion of the combined thiamine in cow's milk is bound to protein and liberated by hydrolysis with pepsin. In the cow, total thiamine of the milk is higher in early lactation than in the later months. As in human milk, the thiamine of cow's milk varies with the amount supplied in the diet, but the cow has the additional possibility of supplementation by thiamine formed by microbiological synthesis in the rumen. One quart of milk contains about one-fourth the daily human adult requirement of thiamine.

*Riboflavin* is the one vitamin for which dairy milk and milk products are the richest everyday source, exceeded in riboflavin concentration only by liver and yeast. The source of this abundance of riboflavin is bacterial

<sup>20</sup> Archibald: *J. Dairy Sci.*, **34**, 1026 (1951).

<sup>20a</sup> Middlesworth, Tuttle, and Threlkeld: *Science*, **118**, 749 (1953).

action in the rumen. In cattle, a day's output of riboflavin in the milk has been found to be up to ten times the dietary intake. Most samples of dairy milk contain between 100 and 200  $\mu\text{g}$ . of riboflavin per 100 ml. Cheese and other milk products, including evaporated milk, are excellent sources of riboflavin. If milk and milk products are excluded from the usual American diet, the riboflavin requirement is not met. The riboflavin of milk and milk products is as completely available to the human organism as is riboflavin taken in simple water solution. This is not true of the riboflavin in some other common foodstuffs.<sup>21</sup>

The riboflavin content of human milk is much lower than that of cow's milk, usually between 20 and 30  $\mu\text{g}$ . per 100 ml. if no supplementary riboflavin is ingested. Since the contribution of riboflavin to the human organism from bacterial synthesis in the large intestine is minimal, the riboflavin content of human milk is determined by the riboflavin of the diet.

*Nicotinic acid* is present in cow's milk in a concentration usually slightly less than 100  $\mu\text{g}$ . per 100 ml. Somewhat higher concentrations are reported for goat and human milk. It is obvious that the recommended daily adult intake of 10 to 15 mg. could not be met with milk alone, and one might wonder how the nursing young avoid deficiency. A part of the answer is that many animals, including man, can meet part of the nicotinic acid requirement by synthesizing it from tryptophan. Pellagra-producing diets have been characterized by low content of tryptophan as well as of nicotinic acid. Milk, although low in nicotinic acid, is high in tryptophan (40 to 50 mg. per 100 ml. in cow's milk).

Cattle appear to be able to meet their entire requirement for *pantothenic acid* by bacterial synthesis in the rumen. Dairy milk contains 300 to 400  $\mu\text{g}$ . of pantothenic acid per 100 ml., human milk about half this amount. The *pyridoxal* group of vitamins (vitamin B<sub>6</sub>) is present in milk in variable amount, most reports giving mean values between 50 and 70  $\mu\text{g}$ . per 100 ml. for cow's milk. *Biotin* is present in milk in quite variable concentrations up to 10  $\mu\text{g}$ . per 100 ml. The mean *folic acid* and *vitamin B<sub>12</sub>* contents<sup>22</sup> for human milk have been reported as 0.71 and 0.41  $\mu\text{g}$ . per liter; for cow's milk, 1.3 and 6.6  $\mu\text{g}$ . per liter, and for goat's milk 2.7 and 0.12  $\mu\text{g}$ . per liter. All the B vitamins mentioned in this paragraph are those of which an uncomplicated dietary deficiency has not been observed in man, and which in large part may be supplied to man by bacterial synthesis in the intestine; hence the values given are of more academic than nutritional significance.

The *ascorbic acid* content of cow's and goat's milk, when fresh, is about 2 mg. per 100 ml., which decreases to less than 1 mg. by the time the milk is made available through usual retail outlets.<sup>23</sup> For infants, and for adults living on milk diets, supplementation with ascorbic acid is necessary for optimal intakes. Human milk, depending somewhat upon the nutrition of the mother, usually runs higher in ascorbic acid than the milk of dairy animals. On intakes of vitamin C ranging from 43 to 106 mg.

<sup>21</sup> Everson, Pearson, and Matteson: *J. Nutrition*, **46**, 45 (1952).

<sup>22</sup> Collins, Harper, Schreiber, and Elvehjem: *J. Nutrition*, **43**, 313 (1951).

<sup>23</sup> Holmes: *J. Am. Dietetic Assoc.*, **27**, 578 (1951).

daily, 16 mothers were found to put out from 19 to 46 mg. of ascorbic acid in the milk per day, at concentrations ranging from 1.9 to 5.8 mg. per 100 ml. (Kon and Mawson).

*Vitamin A*, being fat-soluble in contrast to the vitamins previously mentioned, is found in association with milk fat. Human milk may contain from 50 to somewhat over 200 units of vitamin A per 100 ml., the concentration of the vitamin being correlated with the fat content of the milk. The *carotenoids* which are responsible for the yellow pigmentation of milk fat are to a varying degree *provitamins A*. Human milk contains from 7 to 25  $\mu$ g. of carotenoids per 100 ml. The milk of cattle contains vitamin A and provitamins A in concentrations which, though comparable to those in human milk, are highly variable, depending upon the composition of the feed.

*Vitamin D*, under optimal conditions, may be present in human milk, dairy milk, or milk fat in amounts adequate to prevent rickets in infants and children. Since this is often not the case, supplementation with vitamin D is standard practice in those parts of the world where exposure of infants, mothers, or dairy animals to sunlight is inadequate. Milk is often enriched with vitamin D to provide 400 units per quart.

*Vitamins K* and *vitamins E* are present in measurable amounts in human and dairy milk. The concentrations of these substances in milk are not significant in human nutrition.

## MILK AND HUMAN NUTRITION

The suitability of milk and milk products for human food is a logical consequence of their chemical composition. The history and experience of mankind give further evidence of the value of dairy animals to our well-being. The cow produces a protein food of high biological value and produces it with an extraordinary economy which results from her ability to utilize a high proportion of rough feed in her diet. As an extreme case, she can survive and produce milk on forage alone, although this is not the way to maintain a high milk production. Protein foods are, of course, necessary for man at all ages, but their lack is most disastrous during early childhood shortly after weaning. *Kwashiorkor*, or malignant malnutrition, occurs in children in those areas where the proteins of high biological value supplied by such foods as milk, meat, and egg are lacking, and where starchy foods are the dietary staples.<sup>24</sup> This disease is characterized by extreme fatty degeneration of the liver, with permanent scarring (cirrhosis) in those who survive. Although kwashiorkor is a disease of multiple dietary deficiencies, usually with adequate caloric intake, it responds poorly to vitamin therapy, and is best treated or prevented by protein foods.

Milk has a justified reputation as a "protective" food, meaning that it protects the individual from several possible dietary deficiencies, including those of protein, calcium, and riboflavin. Like many other good things, milk can be used unwisely. Older children require more protein than is supplied by a quart of milk, and it is wise not to depend upon milk

---

<sup>24</sup> Meiklejohn and Passmore: *Ann. Rev. Med.*, 2, 129 (1951).

alone as a protein source, but to supplement it with more concentrated protein foods. It should also be recalled that milk is not a dependable source of iron, thiamine, ascorbic acid, or vitamin D (except vitamin D milk) in the diet of growing children. Iron-deficiency anemia is quite characteristic of infants who have been kept too long on unsupplemented breast or bottle feeding.

The use of *human milk* has obvious advantages in the feeding of human infants, including optimal adaptation to nutritional needs and almost complete freedom from bacterial contamination. In lactation, the first week is critical for the mother, who should avoid overeating or other possible causes of digestive disturbances. Later, the diet should be ample and nutritious, but there need be no excessive gain in the mother's weight. The addition of one quart of dairy milk to her usual diet is a common and usually satisfactory recommendation. The average daily production of milk by the human mother ranges from around 300 ml. in the first week to 900 ml. in the twentieth week. The variation from these mean figures is extreme, and outputs of more than a gallon a day have been reported.

*Cow's milk* is the basis of most prepared foods for infants. The reduction in the mortality of bottle-fed babies has been one of the untrumpeted triumphs of preventive medicine. As recently as 1922, the mortality of bottle-fed babies was four times that of breast-fed babies. At present there is no significant difference. Pasteurization (heating to 143° F. for 30 minutes) destroys pathogenic bacteria without coagulating the whey proteins. This is an adequate method, when combined with proper handling after pasteurization, of rendering the milk suitable as a food for adults. It eliminates the possibility of transmission of brucellosis or bovine tuberculosis to human beings. It is not an adequate treatment of milk for young babies, for whom all milk, whether raw or pasteurized, is customarily boiled. This reduces the toughness of the casein curd (see p. 366) and kills all bacteria. There is no nutritional disadvantage to the boiling of milk other than the complete destruction of ascorbic acid, which is customarily given in a supplementary food.

*Goat's milk* is used as a food to a limited extent in the United States. A considerable amount is produced in small dairies, chiefly for home use. When goat's milk is available on the market, the price is usually higher than that of cow's milk. The nutritive value of goat's milk is so close to that of cow's milk that it is impossible to make a choice on this basis alone. Goat's milk has often been used successfully in the feeding of infants or children who show allergy to cow's milk. Many other therapeutic claims have been made for goat's milk, but acceptable evidence for them is lacking. The claim of easier digestibility compared to cow's milk has some basis in fact, since the fat particles of goat's milk are smaller, and the curd tension (toughness of precipitated casein) is less as compared with unhomogenized cow's milk. One often-mentioned disadvantage of goat's milk is apparently fictitious—so-called "goat's milk anemia." In experiments with both rats and babies, no difference has been found in the outcome of feeding with cow's and goat's milk. Either is nutritionally satisfactory, and both require supplementation with iron and with vitamins C and D. Under the very best stabling conditions for both species,

as for example for the experimental herds at Beltsville, it is possible to keep goats cleaner than cows; hence the bacterial counts of goat's milk are lower under such test conditions. Under ordinary stabling conditions, goat's milk has no less opportunity to be contaminated than cow's milk. Goats are not susceptible to bovine tuberculosis, but otherwise any milk-borne disease can be carried as effectively by goat's milk as by cow's milk; hence pasteurization or boiling is as necessary for the milk of one species as for that of the other. Inspection of cow's milk and of the dairies where it is produced is almost universal in American communities, but goat's milk is often not included in the regulations governing such inspections.

*Evaporated milk* is prepared by concentration under reduced pressure to slightly less than half the original volume. The concentration of dissolved solids is therefore slightly more than twice that of the original milk. For purposes of infant feeding, evaporated milk may be used in half the amount specified for whole milk, reconstituted to the specified volume with boiled water. Most brands of evaporated milk sold at retail are fortified to provide 400 U. S. P. units of vitamin D<sub>1</sub> per reconstituted quart, and this is indicated on the label. Evaporated milk is sterilized at high temperatures after being sealed in cans, and under present-day conditions of manufacture is rarely subject to spoilage from incomplete sterilization. Even though the milk is sterile, undesirable alterations of viscosity may occur on storage, sometimes with separation of proteins into an insoluble gel. These changes are unlikely if evaporated milk is used within two years, and if it is stored at temperatures below 60° F.<sup>25</sup>

*Canned fresh whole milk*, which will keep four to six months without refrigeration, is sterilized by bringing its temperature almost to 300° F. for a few seconds in a specially designed heat-exchanger. The canning is done under sterile conditions. This type of canned milk has no cooked flavor. At the time of this writing, this product is not sold extensively at retail in the United States, but is processed chiefly for the armed services.

The original *condensed milk* (1858) was concentrated by evaporation under reduced pressure and preserved by the addition of sucrose. It was not originally sold in cans, but in bulk after the manner of sale of milk at that time. For many years this product has been available at retail, canned and heat-sterilized. The concentration of milk components in present-day condensed milk is a little higher than in evaporated milk, and the percentage of added sucrose is about 40 per cent.

The better grades of *dried milk* are prepared by very rapid drying under reduced pressure, which preserves the vitamin potency as well as other nutrients. Such products are satisfactory for human food and for infants' formulas, when produced under proper sanitary conditions. Cheaper grades, intended for animal food, are produced under less strict standards of quality and sanitation.

Storage of fluid milk or of milk concentrates at very low temperatures (−5° to −15° F.) is a satisfactory method of preservation which does not produce undesirable changes in flavor or physical properties.<sup>26</sup> The use

<sup>25</sup> Webb, Deysher, and Potter: *J. Dairy Sci.*, **34**, 1111 (1951).

<sup>26</sup> Tracy, Hetrick, and Krienke: *J. Dairy Sci.*, **33**, 832 (1950).

of cathode rays has been found effective in sterilizing milk, and is claimed to be without effect upon flavor.<sup>27</sup>

State laws in the United States require that *ice cream* contain a specified percentage of milk fat, the percentage varying from 8 to 14 in different jurisdictions. Frozen preparations with lower fat content are sold as ice milk or sherbet.

Determining the freezing point of milk is a simple physical test which reveals dilution with water. Observation in a mixed milk specimen of a freezing point higher than the limiting value of  $-0.520^{\circ}\text{C}$ . indicates that such dilution has been made. If the sample is from a single cow, there is a remote chance that this limiting value may be exceeded without the addition of water. If the sample is a mixture of the milk of six or more cows, a freezing point above the limiting value is definite evidence of watering, and if the sample is from forty cows or more, a freezing point above  $-0.540^{\circ}\text{C}$ . raises strong suspicion of watering.<sup>28</sup>

**Economics.** The milk-producing cows of the United States number close to 25,000,000 and their output is estimated at over 14,000,000,000 gallons per year, which brings to American dairymen an annual gross income of more than \$3,760,000,000. Estimates released by the Milk Industry Foundation apportion the 1950 milk output as having been used as follows:

|                                       |       |
|---------------------------------------|-------|
| Fluid milk and cream                  |       |
| sold in cities and villages           | 37.3% |
| used on farms where produced          | 10.1% |
| Butter                                |       |
| creamery-made                         | 22.7% |
| farm-made                             | 4.3%  |
| Cheese                                | 9.5%  |
| Ice cream                             | 5.1%  |
| Evaporated, condensed, and dried milk | 6.4%  |
| Milk fed to calves on farms           | 2.7%  |
| Milk for other uses                   | 1.9%  |

The figures above do not tell the whole story, since skim milk, buttermilk, and whey remain after cream, butter, and cheese have been made. Lactose for use in the manufacture of food and medicinal products is separated from such residues and marketed at a rate of 40,000,000 pounds a year in the United States. About half this amount of casein is similarly obtained, and is used for human and animal food, and in pharmaceutical, paper, paint, and adhesive products. Hydrolyzates of casein are used in special diets, in food flavoring, and as nutrients in industrial microbiology. The whey proteins are also separated, and are used in food products and for many industrial purposes.

## EXPERIMENTS ON MILK

**1. Phosphatase Test for Pasteurization (Cornell Method<sup>29</sup>): Principle.** The destructive effect of heat on the natural phosphatase in raw milk is used as the basis for testing the efficiency of pasteurization. Phosphatase activity is measured by the

<sup>27</sup> *Chem. Eng. News*, 29, 2818 (1951).

<sup>28</sup> Lythgoe: *J. Assoc. Offic. Agr. Chemists*, 55, 442 (1952).

<sup>29</sup> Kosikowsky: *J. Dairy Sci.*, 34, 1151 (1951). Reproduced by permission of the author and the *Journal of Dairy Science*.

hydrolysis of disodium phenylphosphate and colorimetric estimation of the released phenol. Dairy product samples are incubated with the substrate buffered at pH 9.5 to 9.7, and then the protein is precipitated. After filtration, the filtrate is brought back to an alkaline reaction with carbonate, and BQC<sup>30</sup> is added. Blue color is produced if sufficient phosphatase was present in the milk to split the disodium phenylphosphate substrate during incubation. The procedure as given here applies to milk. With minor modifications (given in the original paper) the Cornell test can be applied to other dairy products.

**Procedure.**<sup>31</sup> a. **SAMPLING AND INCUBATING (LONG METHOD).** For milk and other fluid dairy products, 1 ml. of milk or milk product is transferred to a 25 × 150 mm. test tube. Add 10 ml. of warm (40° C.) carbonate buffer substrate and 4 drops of U. S. P. chloroform. A piece of parchment paper is fitted over the tube with the aid of a rubber band, and the milk is incubated at 32° to 37° C. for 18 to 24 hours.

b. **PRECIPITATION.** After incubation, 1 ml. of trichloroacetic—HCl precipitant is slowly added to the tube. The resulting protein precipitate is filtered off through Whatman No. 42 paper (11 cm.).

c. **COLOR DEVELOPMENT.** Five ml. of the clear filtrate is pipetted into a 16 × 150 mm. test tube. One ml. of CuSO<sub>4</sub>—"Calgon" solution and 5 ml. of 8 per cent Na<sub>2</sub>CO<sub>3</sub> are added. Then 2 drops of BQC solution are placed in this solution. The tubes after mixing are inserted in a water bath at 37° C. for 15 minutes. Color development is measured after this interval against suitable color standards or in a colorimeter.

**INTERPRETATION OF RESULTS.** All final color readings are, after consideration of control values, multiplied by a factor of 1.2 to convert to μg. phenol per 0.5 ml. Any

<sup>30</sup> See 2,6-Dibromoquinonechloroimine solution (BQC) under footnote 31.

<sup>31</sup> *Reagents and Materials:*

*Carbonate Buffer Substrate:* Dissolve 11.50 g. anhydrous Na<sub>2</sub>CO<sub>3</sub>, 10.15 g. anhydrous NaHCO<sub>3</sub>, and 1.09 g. pure disodium phenylphosphate in water and make up to 1 liter (pH = 9.80).

*Trichloroacetic—hydrochloric acid precipitant:* Dissolve 25 g. trichloroacetic acid crystals in water, make up to 50 ml. with water; add 50 ml. conc. HCl (approx. 36 per cent) and mix thoroughly.

*Sodium carbonate solution (8 per cent):* Dissolve 80 g. anhydrous Na<sub>2</sub>CO<sub>3</sub> in water and make up to 1 liter.

*Copper sulfate—"Calgon" solution:* Dissolve 500 mg. CuSO<sub>4</sub>·5H<sub>2</sub>O and 20 g. "Calgon" (sodium hexametaphosphate) crystals (tech.) in water and make up to 1 liter.

*2,6-Dibromoquinonechloroimine solution (BQC):* Dissolve 50 mg. BQC in 10 ml. absolute ethyl or methyl alcohol and store in dark bottles.

*Color standards:* Make the following solutions as preliminary to making standards—

a. *Stock phenol solution:* Dissolve 1 g. phenol crystals in water and make up to 1 liter.

b. *Buffer solution:* Make 1 liter of carbonate buffer containing 11.50 g. Na<sub>2</sub>CO<sub>3</sub> and 10.15 g. NaHCO<sub>3</sub>.

c. *Diluted phenol solution:* Using 4 ml. of stock phenol solution (a), make up to 500 ml. with buffer solution (b). This solution contains 8 μg. phenol per ml.

*Preparation of color standards:* Place in clean 16 × 150 mm. test tubes 0.5 to 5 ml. portions of Diluted Phenol Solution (c). Add enough Buffer (b) so that total volume of liquid in each tube is 10 ml. Then add 1 ml. of copper sulfate—"Calgon" solution to each tube. Finally, add 2 drops of BQC and 4 drops U. S. P. chloroform and mix. Let stand for 15 minutes at 37° C. Seal tubes with paraffin wax and store in refrigerator. Tubes containing 0.5, 1.0, 1.5, 2.5, and 5.0 ml. portions of diluted phenol solution will produce standards of 4.0, 8.0, 12.0, 20.0, and 40.0 μg., respectively, after final color development. Color standards of 2.0 and 5.0 μg. can be easily obtained by making 4.0 and 20.0 μg. solutions without color development and diluting these with sufficient Buffer Solution (b). Color is then developed in 10-ml. portions by adding copper sulfate—"Calgon" solution and BQC.

To obtain alcohol color standards, 5 ml. of butyl alcohol are added to a duplicate series of final aqueous color standards. The tubes are inverted ten times to extract color, and the cork stoppers are sealed with wax.

value over  $5\mu\text{g}$ . per 0.5 ml. milk or other fluid dairy product for the long procedure, or  $2\mu\text{g}$ . per 0.5 ml. for the short method, is tentatively considered to indicate either underpasteurization or the presence of raw-milk products, or a combination thereof. The short method, even to the extent of using samples of the same size, is conducted in the same way as the long method except that (a) incubation is carried out for 1 hour at  $37^\circ$  to  $38^\circ\text{C}$ ., and (b) chloroform is omitted.

**CONTROLS FOR LONG AND SHORT METHODS.** One ml. of milk, preferably from pasteurized stock, is placed in a tube, heated to  $78^\circ\text{C}$ . ( $170^\circ\text{F}$ ). for 15 seconds in a water bath and then cooled immediately. This heated control is tested by the same method as employed for samples of unknown history.

**ALCOHOL EXTRACTION.** If necessary, butyl alcohol extraction may be used in either the long or short method, especially on critical values. Five ml. of *n*-butyl alcohol is added to the test tube containing the aqueous colored solutions, and the latter is inverted ten times. The clear layer appears without centrifuging and is compared against alcohol standards. Alcohol extraction is preferred when a colorimeter is not used, as aqueous phenol standards for all methods deteriorate, as a rule, relatively rapidly.

**2. Influence of Gastric Rennin on Milk.** Prepare a series of five tubes as follows:

a. 5 ml. of fresh milk + 0.2 per cent HCl (add drop by drop until a precipitate forms).

b. 5 ml. of fresh milk + 5 drops of rennin solution.<sup>32</sup>

c. 5 ml. of fresh milk + 10 drops of 0.5 per cent  $\text{Na}_2\text{CO}_3$ .

d. 5 ml. of fresh milk + 10 drops of ammonium oxalate solution.

e. 5 ml. of fresh milk + 5 drops of 0.2 per cent HCl.

To each of the tubes (c), (d), and (e) add 5 drops of rennin solution. Place the whole series of five tubes at  $40^\circ\text{C}$ . and after 10 to 15 minutes note what is occurring in the different tubes. Give a reason for each particular result.

**3. Preparation of Casein.**<sup>33</sup> Into a 600-ml. beaker introduce 200 ml. of skimmed (or centrifuged) milk. Add an equal volume of water. Add from a pipet very carefully, drop by drop with thorough stirring, 10 per cent HCl until a flocculent precipitate forms. (Casein precipitates best at a point slightly more acid than its isoelectric point of pH 4.55.) From 3 to 5 ml. of acid are commonly required. In milk, casein functions as an acid and exists as K and Ca caseinates, from which compounds it is released by the acid. As the isoelectric point is passed, however, the casein begins to function as a base and go into solution as casein hydrochloride. Hence excess of acid must be avoided. If too much acid be added, run in, drop by drop, 10 per cent NaOH solution until precipitation occurs and a clear supernatant fluid is obtained. Allow the precipitate to settle, decant the supernatant fluid, and reserve it for use in later (4-6) experiments. Filter off the precipitate of casein and remove the excess of moisture by pressing it between filter papers. Transfer the casein to a small beaker, add enough 95 per cent alcohol to cover it, and stir for a few moments. Filter, and press the precipitate between filter papers to remove the alcohol. Repeat the extraction with alcohol, making sure that the casein is in a finely divided condition. Transfer the casein again to a small

<sup>32</sup> Any commercial rennin or rennet preparation or an extract of the gastric mucosa of the pig may be employed.

<sup>33</sup> For the preparation of very pure casein it is better if the milk be centrifuged several times in a separator, then a small amount of dilute alkali added, and the milk centrifuged several times more. Casein is also purified by repeated solution in dilute alkali and reprecipitation by acid.

dry beaker, cover the precipitate with ether and heat on a water bath, with any flames turned out, for ten minutes, stirring continuously. Filter (reserve the filtrate), and press the precipitate as dry as possible between filter papers. Open the papers and allow the ether to evaporate spontaneously. Grind the precipitate to a powder in a mortar. Upon the casein prepared in this way make the following tests:

a. **SOLUBILITY.** Try the solubility in water, sodium chloride, dilute acid, and alkali.

b. **MILLON'S REACTION.** Make the test according to the directions given on p. 169.

c. **CYSTINE AND CYSTEINE SULFUR.** Test for cystine and cysteine sulfur according to the directions given on p. 168.

d. **FUSION TEST FOR PHOSPHORUS.** Test for phosphorus by fusion according to the directions given on p. 212.

4. **Coagulable Proteins of Milk.** Place the filtrate from the original casein precipitate in a casserole and heat on a wire gauze over a free flame. As the

FIG. 63. LACTOSE.

solution concentrates, a coagulum consisting of lactalbumin and lactoglobulin will form. Continue to concentrate the solution until the volume is about one-half that of the original solution. Filter off the coagulable proteins (reserve the filtrate) and test them as follows:

a. **MILLON'S REACTION.** Make the test according to the directions given on p. 169.

b. **CYSTINE AND CYSTEINE SULFUR.** Make the test according to the directions given on p. 168. Do the coagulable proteins differ from casein in their reaction to this test? Why?

5. **Detection of Calcium Phosphate.** Evaporate the filtrate from the coagulable proteins, on a water bath, until crystals begin to form. It may be necessary to concentrate to 15 ml. before any crystallization will be observed. Cool the solution, filter off the crystals (reserve the filtrate), and test them as follows:

a. **MICROSCOPICAL EXAMINATION.** Examine the crystals and compare them with those in Fig. 64.

b. Dissolve the crystals in nitric acid. Test part of the acid solution for phosphates. Render the remainder of the solution slightly alkaline with ammonia, then acidify with acetic acid and add ammonium oxalate. Examine the crystals under the microscope and compare them with those in Fig. 230, p. 855.

6. *Detection of Lactose.* Concentrate the filtrate from the calcium phosphate until it is of a syruplike consistency, and pour it into several volumes of acetone to precipitate the lactose in crystalline form.

a. MICROSCOPICAL EXAMINATION. Examine the crystals and compare them with those in Fig. 63.

b. BENEDICT'S TEST. Try Benedict's test upon the mother liquor.

c. PHENYLHYDRAZINE TEST. Apply the phenylhydrazine test to some of the mother liquor according to the directions given on p. 63.

7. *Milk Fat.* Evaporate the ether filtrate from the casein (Exp. 3) and observe the fatty residue. The milk fat was carried down with the precipitate of casein and was removed when the latter was treated with ether. If centrifuged milk is used in the preparation of the casein the amount of fat in the ether filtrate may be very small.

FIG. 64. CALCIUM PHOSPHATE.

8. *Saponification of Butter.* Dissolve a small amount of butter in alcohol made strongly alkaline with potassium hydroxide. Place the alcoholic-potash solution in a casserole, add about 100 ml. of water and boil for 10 to 15 minutes or until the odor of alcohol cannot be detected. Place the casserole in a hood and neutralize the solution with sulfuric

acid. Note the odor of volatile fatty acids, particularly butyric acid. Under certain conditions the odor of ethyl butyrate may also be detected.

## QUANTITATIVE ANALYSIS OF MILK<sup>34</sup>

1. *Collection of Human Milk for Analysis.* There are two methods of obtaining samples of breast milk for analysis.

FIRST METHOD. Express all the milk from one breast and mix thoroughly.

SECOND METHOD. Draw one ounce of milk before nursing and one ounce after nursing. Mix the two samples thoroughly. The best time for obtaining samples is 9 to 10 A.M.

2. *Specific Gravity.* This may be determined accurately by means of a pycnometer or more conveniently by means of a Soxhlet, Veith, or Quevenne lactometer. A lactometer reading of 32° denotes a specific gravity of 1.032. The determination should be made at about 60° F. (15.6° C.) and the lactometer reading corrected by adding or subtracting 0.1° for every degree F. above or below that temperature.

### 3. Fat.

a. BABCOCK'S CENTRIFUGAL METHOD: PRINCIPLE. This method involves the breaking of the emulsion of fat in milk by means of concentrated sulfuric acid, centrifugation of the acid solution in the special tube shown in Fig. 65, and the subsequent reading of the percentage of fat in the graduated neck. Larger Babcock bottles are commonly

<sup>34</sup> *Official and Tentative Methods of Analysis*, 7th ed., Washington, D. C., Assoc. of Official Agricultural Chemists, 1950.

used for testing cow's milk or cream; these are supplied with pipets calibrated to deliver 18- or 9-g. charges, respectively. The method is accurate to within 0.5 per cent.

**Procedure.** By means of a special narrow pipet, introduce milk into the tube up to the 5-ml. mark. Now add sufficient sulfuric acid (sp. gr. 1.83–1.834) to fill the body of the tube and rotate the tube to secure a homogeneous acid-milk solution. Fill the neck of the tube with an acid-alcohol mixture.<sup>35</sup> Centrifuge the tube and contents for one to two minutes and read off the percentage of fat by means of the graduated neck of the tube. If the top of the fat column is not at zero it may be brought there by the addition of hot water and a moment's recentrifugation.

In case very rich milk (over 5 per cent fat) is under examination, it may be diluted with an equal volume of water before examination and the fat percentage multiplied by 2. In the ex-

FLASK.

Designed to permit weighing, extraction, and decantation without transfer of sample.

amination of cream it is customary to dilute the sample with four volumes of water and multiply the resultant fat value by 5.

b. ROESE-GOTTLIEB METHOD: PRINCIPLE. The milk is made alkaline and extracted repeatedly with petroleum benzin and the filtered extract evaporated to dryness in a tared flask. This method, together with the Babcock procedure, is "official" in the A.O.A.C. Book of Methods (see footnote 34, p. 236) and is adaptable to butter, ice cream, dried milk, etc.

**Procedure.** Transfer 10 g. of the sample to a Röhrig tube (Fig. 66) or a similar apparatus (Mojonnier flasks<sup>36</sup> (Fig. 67) are widely used in dairy laboratories), add 1.25 ml. of  $\text{NH}_4\text{OH}$  (2 ml. if the sample is sour), and mix thoroughly. Add 10 ml. of 95 per cent alcohol and mix well. Add 25 ml. of

<sup>35</sup> This mixture consists of equal volumes of amyl alcohol and concentrated hydrochloric acid.

<sup>36</sup> Obtained from Mojonnier Bros. Co., 4601 West Ohio St., Chicago 44, Ill.

ether, shake vigorously for 30 seconds, add 25 ml. of petroleum benzin (redistilled slowly at a temperature below 65° C.), and shake again for 30 seconds. Let stand 20 minutes, or until the upper liquid is practically clear. Draw off as much as possible of the ether-fat solution (usually 0.5 to 0.8 ml. will be left) into a flask through a small, quick-acting filter. Again extract the liquid remaining in the tube, this time with 15 ml. of each solvent; shake vigorously 30 seconds after each addition and allow to settle. Draw off the clear solution through the small filter into the same flask as before and wash

FIG. 68.  
SOXHLET  
EXTRACTION  
APPARATUS.

the tip of the spigot, the funnel, and the filter with a few ml. of a mixture of the two solvents, in equal parts, free from suspended  $H_2O$ . To insure complete removal of the fat, a third extraction is necessary. (This third extraction yields less than 1 mg. of fat if the previous solutions have been drawn off closely.) Add a glass bead and evaporate the ethers slowly on a warm surface; then dry the fat in a boiling water oven to constant weight. Weigh the flask with a similar flask as a counterpoise. Do not wipe the flask immediately before weighing. Remove the fat completely with petroleum benzin. Deduct the weight of the dried flask with residue and bead to obtain the weight of fat. Finally, correct this weight by a blank determination on the reagents used.

c. SOXHLET METHOD. This classical procedure is suitable for the determination of fat in solid materials such as dried milk. (Fig. 68.)

4. *Total Solids*. Introduce 2 to 5 g. of milk into a weighed, flat-bottomed platinum dish<sup>37</sup> (which may, if desired, contain 15 to 20 g. of pure, dry sand spread over the bottom) and quickly ascertain the weight to milligrams. Expel the major portion of the water by heating the open dish on a water bath and continue the heating in an air bath or water oven at 97° to 100° C. until the weight is constant. (If platinum dishes are employed this residue may be used in the determination of ash according to the method described below.)

CALCULATION.<sup>38</sup> Divide the weight of the residue by the weight of milk used. The quotient multiplied by 100 gives the percentage of solids contained in the milk examined.

5. *Ash*. Heat the dry solids from 2 to 5 g. of milk, obtained according to the method just given, over a very low flame<sup>39</sup> until a white or light-gray ash is obtained. If the determination is made directly on fluid milk, weigh quickly about 20 ml., add 6 ml. concentrated  $HNO_3$ , evaporate, and ignite as above. Cool the dish in a desiccator and weigh.

6. *Protein*. Introduce a known weight of milk (5 to 10 g.) into a 500-ml. Kjeldahl digestion flask and add 20 ml. of concentrated sulfuric acid and

<sup>37</sup> Lead or aluminum foil dishes (which are much cheaper) make a very satisfactory substitute for the platinum dishes.

<sup>38</sup> The percentage of total solids may be calculated from the specific gravity and percentage of fat by means of the following formula:

$$S = 0.25 L + 1.2 F$$

$S$  = total solids.  $L$  = lactometer reading (third and fourth decimal places of specific gravity).  $F$  = fat content.

<sup>39</sup> Great care should be used in this ignition, the dish at no time being heated above a faint redness, since chlorides may volatilize.

about 0.2 g. of copper sulfate. Expel the major portion of the water by heating over a low flame, and finally use a full flame and allow the mixture to boil one to two hours. Complete the determination according to the directions given under the Kjeldahl Method, p. 874. If large amounts of milk are not available, a micro method may be used (see p. 880).

CALCULATION. Multiply the total nitrogen content by the factor 6.38<sup>40</sup> to obtain the protein content of the milk examined.

**7. Casein.** To 10.5 ml. (or a weighed equivalent) of fresh milk in a beaker, add 90 ml. of warm water (40° to 42° C.) and 1.5 ml. of 10 per cent acetic acid and stir. After 5 minutes' standing decant on an acid-washed filter, and wash the precipitate by decantation several times with cold water. Transfer the precipitate to the filter and repeat the washing twice. The filtrate should be clear or very nearly so. If the first portions are not clear, repeat the filtration and complete the washing of the precipitate. Determine the nitrogen content in the washed precipitate and filter, as directed in Exp. 6.

CALCULATION. Total N  $\times$  6.38 = casein content of aliquot.

**8. Hart's Casein Method.** Introduce 10.5 ml. of milk into a 200-ml. Erlenmeyer flask and add 75 ml. of distilled water and 1.0 to 1.5 ml. of 10 per cent acetic acid.<sup>41</sup> Mix the contents by giving the flask a vigorous rotary motion. The precipitated casein is now filtered off upon a 9- to 11-cm. filter paper.<sup>42</sup> Wash out the absorbed and loosely combined acetic acid by means of cold water. Continue the washing of both the casein on the filter and that adhering to the flask, until the wash water has reached a volume of at least 250 ml.

Now return the precipitate and paper to the original Erlenmeyer flask, add 75 to 80 ml. of neutral (carbon dioxide-free) water, 10 ml. of 0.1 N potassium hydroxide, and a few drops of phenolphthalein. Stopper the flask and shake it vigorously, by hand or machine, until the casein has been brought into solution.<sup>43</sup> Rinse the stopper with neutral (carbon dioxide-free) water and titrate the alkaline casein solution at once with 0.1 N hydrochloric acid until there is a disappearance of all red color.<sup>44</sup>

CALCULATION. Subtract the corrected<sup>44</sup> acid reading from the 10 ml. of alkali used. The difference is the percentage of casein in the milk. For example, if it takes 6.7 ml. of 0.1 N hydrochloric acid to titrate the alkaline solution to the end point and the check test was equivalent to 0.2 ml. of 0.1 N acid, the casein value would be obtained as follows:  $10 - (6.7 + 0.2) = 3.1$  per cent casein.

**9. Coagulable Protein.** Exactly neutralize the filtrate obtained under Exp. 7 with 10 per cent NaOH solution, add 0.3 ml. of 10 per cent acetic acid, and

<sup>40</sup> The usual factor employed for the calculation of protein content of average or mixed foods from the nitrogen content is 6.25. It is based on the observation that proteins contain on the average 16 per cent nitrogen. The factor 6.38 is used to calculate the protein content from the total nitrogen, since the total protein constituents of milk have a mean nitrogen content of 15.7 per cent.

<sup>41</sup> In general 1.5 ml. of acetic acid gives a clear solution which filters nicely, but occasionally, when the milk has a low casein value, it is advisable to use less acetic acid.

<sup>42</sup> The process of filtration may be retarded through the packing of the casein mass upon the filter paper. In this case conduct a fine stream of cold water against the upper point of contact of filter paper and casein. By this means the casein precipitate is loosened and gathers in the apex of the filter. This procedure is very essential. It is not necessary to remove the casein which adheres to the interior of the flask.

<sup>43</sup> Solution is indicated by the disappearance of the white casein particles which would otherwise settle to the bottom of the flask.

<sup>44</sup> A check test should be run parallel with the entire determination. Even with special precautions as to neutrality, it is generally found that an acid check of 0.2 to 0.3 ml. will be obtained. This check titration should be added to the volume of acid used in titration.

heat on a steam bath until the protein is completely precipitated. Collect the precipitate on an acid-washed filter, wash with cold  $H_2O$ , and determine the nitrogen as directed under Exp. 6.

CALCULATION. Multiply the total nitrogen by the factor 6.38 to obtain the albumin and globulin content.

**10. Lactose.**<sup>45</sup> To about 350 ml. of water in a beaker add 20 g. of milk, mix thoroughly, acidify the fluid with about 2 ml. of 10 per cent acetic acid, and stir the acidified mixture continuously until a flocculent precipitate forms. At this point the reaction should be distinctly acid to litmus. Heat the solution to boiling for one-half hour, filter, rinse the beaker thoroughly, and wash the precipitated proteins and the adherent fat with hot water. Combine the filtrate and wash water and concentrate the mixture to about 150 ml. Cool the solution and dilute it to 200 ml. in a volumetric flask. Titrate this sugar solution according to directions given under Benedict's Method (see p. 919).

Myers recommends the following procedure for the determination of lactose in milk. One part of milk is mixed with an equal volume of phosphotungstic acid solution (70.0 g. of acid and 200 ml. of concentrated HCl in 1 liter of water) and 2 to 3 parts of water. Mix well, filter until clear, and titrate the clear filtrate against Benedict's solution (25 ml. reduced by 67 mg. of lactose).

BOCK'S METHOD FOR LACTOSE IN MILK. Pipet 20 ml. of milk into a 100-ml. volumetric flask. From a pipet or buret add 12 ml. of 10 per cent sodium tungstate and 12 ml. of  $\frac{2}{3}$  N sulfuric acid. Mix by rotating the flask, dilute to the mark, and filter. Determine the lactose in the filtrate by titration with Benedict's solution.

CALCULATION. Make the calculation in the above titration methods, according to directions given under Benedict's Method (see p. 920), bearing in mind that 25 ml. of Benedict's solution are completely reduced by 0.067 g. of lactose.

### 11. Micro Method for Lactose in Milk.

PRINCIPLE. Lactose is determined on the protein-free filtrate of milk by a copper reduction method, following the method of Folin and Wu for blood sugar. This method is well suited to routine analyses.

**Procedure.** Introduce 1.0 ml. of milk into a 100-ml. volumetric flask, add 2 ml. of 10 per cent sodium tungstate. Add gradually 2 ml. of  $\frac{2}{3}$  N sulfuric acid (or 16 ml. of N/12 acid), mix well, and let stand 5 minutes. Dilute to the mark with water and filter. Into a Folin-Wu sugar tube introduce 1 ml. of the filtrate and 1 ml. of water. Into another tube place 2 ml. of standard lactose solution.<sup>46</sup> Add 2 ml. of the Folin-Wu alkaline copper solution (see p. 568) to each tube, and heat in boiling water for 8 minutes. Cool and add 4 ml. of acid molybdate reagent (see p. 568) to each tube. After 1 minute, add diluted acid molybdate solution (1:4) to the 25-ml. mark, mix, and compare in the colorimeter.

CALCULATION.

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.6 \times \frac{100}{0.01} \times \frac{1}{1000} = \text{Per cent lactose}$$

<sup>45</sup> A method for lactose suitable for tissue analysis, or where other sugars may be present in significant amounts, is described by Malpress and Morrison: *Biochem. J.*, **45**, 455 (1949).

<sup>46</sup> Prepare a stock standard solution by dissolving 1 g. of lactose in 0.2 per cent benzoic acid and making up to a volume of 100 ml. The working standard is prepared by diluting 3 ml. of the stock solution to 100 ml. with 0.2 per cent benzoic acid (2 ml. = 0.6 mg. lactose).

# Epithelial and Connective Tissues: Bone and Teeth

### EPITHELIAL TISSUE (KERATIN)

The major portion of hair, horn, hoof, feathers, nails, and the epidermal layer of the skin is made up of albuminoid proteins called keratins. As a class the keratins are characterized by their extreme insolubility in the usual protein solvents, their lack of digestibility, and their high sulfur content, most of which is in the form of cystine. These characteristics are not unrelated; the keratin molecule is considered to consist of closely packed polypeptide chains which are held together by the disulfide bond of cystine, the resistance to solvents and enzymes being associated with the close packing of the chains. This view is supported by the fact that if wool, for example, is ground to a fine powder by mechanical means it becomes more soluble and more digestible.

According to Block the various keratins may be further characterized as eukeratins and pseudokeratins. The eukeratins contain, in addition to other amino acids, the amino acids histidine, lysine, and arginine in the approximate ratio of 1:4:12, with from 3 to 5 per cent sulfur, nearly all of which is cystine. They are found largely in the hair, nails, feathers, horn, etc. The pseudokeratins, found chiefly in the skin and nervous tissue, contain less sulfur, from 1 to 3 per cent, and do not show the same histidine:lysine:arginine ratios as the eukeratins. It has been shown by x-ray crystallography that the intramolecular spatial arrangement of keratin can be modified under the influence of pressure or stretching. Such differences in molecular configuration of keratin may exist in the varied anatomic forms of epithelial tissue.

The keratins are not acted upon by proteolytic enzymes. This is perhaps due more to lack of physical accessibility to the proteolytic enzymes than to lack of specific types of peptide linkages. Hence if the molecular structure of keratin is changed through chemical or mechanical means these enzymes digest the resultant product quite readily. The keratins appear to be digestible by an enzyme in the intestine of the clothes moth at pH 9 in the presence of the reducing medium yielded by the  $\text{H}_2\text{S}$  liberated through bacterial action in the intestine.

The composition of human hair is influenced by its color and by the race, sex, age, and purity of breeding of the individual.<sup>1</sup> It may be differentiated from all other animal hair or wool by its high content of cystine.

---

<sup>1</sup> Rutherford and Hawk: *J. Biol. Chem.*, 3, 459 (1907).

Most of the S of hair is in the form of cystine, with some cysteine usually present. Human hair contains from 13 to 19 per cent of cystine, sheep's wool 8 to 14 per cent, and feathers 7 to 12 per cent. It is claimed that the vitamins inositol, nicotinic acid, pantothenic acid, and riboflavin are present in normal rat and human hair in about the same ratio as in other tissues.<sup>2</sup>

From the analyses of the skin of the dog, rabbit, and man for mineral constituents, it has been shown that there is an individual variability in composition in the same species as well as distinct differences among different species. The addition of cystine to a diet deficient in this amino acid appears to favor the growth of hair to a greater extent than it affects the growth of body tissue as a whole.

Permanent waving is believed to rest upon a change in the structure of the keratin molecule. The damp heat used in the waving process opens up the disulfide bonds of the keratin. If the hair be artificially curled while in this condition, then dried, the disulfide bonds again form and the wave is automatically held in position. On the other hand if the disulfide groups are changed to sulfhydryl groups by reduction the permanent wave may be made without resorting to heat. Hence the so-called "cold" wave.

The addition of cystine to a sheep's diet will improve the weight and quality of the wool of the animal. In rats, para-aminobenzoic acid is also reported to have prevented the graying of hair. Such findings on lower animals have not been successfully duplicated in controlled observations on human beings.

**Hyaluronic Acid and Hyaluronidase.** So-called *mucopolysaccharides* occur in epithelial and connective tissues. The most important member of this group is *hyaluronic acid*. This may be hydrolyzed by the enzyme *hyaluronidase*.<sup>3</sup> This enzyme was originally termed the *spreading factor* as it was thought to be importantly related to the spread of disease germs in the body. It seems that the hyaluronic acid present in the intercellular substance offers resistance to the spread of harmful microorganisms. However, many such microorganisms manufacture hyaluronidase, which renders hyaluronic acid more or less impotent, permitting the harmful germ to enter the tissues. Thus in rheumatic fever it has been claimed that the therapeutic use of salicylates inhibits the action of hyaluronidase. The intact hyaluronic acid then acts to prevent invasion of the tissues.

In pure form, hyaluronidase, which is also present in spermatozoa, leech heads, and the venom of snakes and bees, has been used clinically to facilitate the hypodermic administration of large volumes of fluids (*hypodermoclysis*). To assist the penetration of certain drugs into mucous membranes, to combat the formation of renal calculi, to speed recovery from painful ankle sprains, and to aid in spreading the effect of local anesthetics over a larger area—these are other clinical functions ascribed to this enzyme. Evidence has accumulated which has cast some doubt upon the supposed efficiency of hyaluronidase in hypodermoclysis.<sup>4</sup>

## EXPERIMENTS ON EPITHELIAL TISSUE (KERATIN)

Horn shavings or nail parings may be used in the experiments which follow:

1. *Millon's Reaction.*
2. *Xanthoproteic Reaction.*
3. *Glyoxylic Acid Reaction (Hopkins-Cole).*
4. *Test for Cystine and Cysteine Sulfur.*

What amino acids do these tests show to be present in keratin?

## CONNECTIVE TISSUE

### I. WHITE FIBROUS TISSUE

The principal solid constituent of white fibrous connective tissue is the albuminoid collagen. This substance is also found in smaller percentage in cartilage, bone, and ligament, but the collagen from the various sources is not identical in composition. In common with the keratins, collagen is insoluble in the usual protein solvents, presumably because of the close packing of the polypeptide chains, as with the keratins. It differs from keratin in containing much less sulfur. Analyses show only 0.1 per cent cystine and 0.9 per cent methionine. It contains no tryptophan and very little tyrosine. It has been estimated that glycine represents one-third of all the amino acid residues in the collagen molecule; a second third of the molecule is composed of proline and hydroxyproline, the other amino acids making up the remainder of the molecule. It is digested slowly by pepsin-HCl but by trypsin only at temperatures above 40° C. or after previous action of pepsin. One of the chief characteristics of collagen is the property of being converted by boiling acid or water to gelatin. The process does not seem to be one of hydrolysis since there is no increase in amino nitrogen. Some intramolecular change may occur, but the x-ray diagram does not change. This suggests that the alteration may be largely a physical one. The amino acid composition is essentially that of gelatin (see p. 122).

In vitamin C (ascorbic acid) deficiency (scurvy) the intercellular cement substances are not deposited in a normal manner. It is believed that in this condition there is a tendency to hemorrhage and to the slow healing of wounds because of the presence of abnormal collagen. In this connection Robertson<sup>5</sup> reports no significant differences in the collagen content of skin, liver, lung, kidney, spleen, costochondral junctions, and teeth of normal and acutely and chronically scorbutic guinea pigs. The same author<sup>6</sup> has shown that when guinea pigs in various nutritional states were fed glycine-N<sup>15</sup> the collagen isolated from liver, lung, muscle, skin, and bone contained N<sup>15</sup> in varying concentrations. The glycine isolated from the collagen of skin, muscle, and bone also contained an excess

<sup>5</sup> Robertson: *J. Biol. Chem.*, **187**, 673 (1950).

<sup>6</sup> *Ibid.*, **197**, 495 (1952).

of the isotope. The concept of *collagen diseases* has received much attention. A wide variety of dissimilar diseases give definite evidence of fibrinoid changes.<sup>7</sup> Hence the clinician has been warned that no special emphasis should be placed upon the occurrence of these changes and the clinical usefulness of the term “collagen disease” is questioned.

In the preparation of leather the collagen of the animal hide is purified and tanned. Certain precipitating agents such as tannic acid and the salts of heavy metals bring about the *tanning*.

The form of white fibrous tissue most satisfactory for general experiments is the tendo achillis of the ox. The fresh tissue has the following composition:

|                                      |               |
|--------------------------------------|---------------|
| Water.....                           | 62.9 per cent |
| Solids.....                          | 37.1          |
| Inorganic matter.....                | 0.5           |
| Organic matter.....                  | 36.6          |
| Fatty substance (ether-soluble)..... | 1.0           |
| Coagulable protein.....              | 0.2           |
| Mucoid.....                          | 1.3           |
| Elastin.....                         | 1.6           |
| Collagen.....                        | 31.6          |
| Extractives, etc.....                | 0.9           |

The mucoid just mentioned is called tendomucoid and is a glycoprotein. It possesses properties similar to those of other connective-tissue mucoids, e.g., osseomucoid and chondromucoid.

Gelatin, the substance which results from the treatment of collagen with boiling water or boiling dilute acids, is sometimes classed as an albuminoid. It is probably better to consider gelatin a protein derivative not properly belonging to any of the recognized classes of proteins. Gelatin differs from the keratins and collagen in having a much simpler physical structure and in being easily soluble and digestible. In fact a large part of a gelatin solution can pass through membranes such as the walls of capillaries, because of its small molecular weight. Gelatin is nonantigenic and is not a complete protein from the nutritional point of view, since it is lacking in tryptophan and low or lacking in certain other amino acids (see p. 122). Thus it is not satisfactory as the sole dietary protein, but because of its ease of digestion and absorption it is used as an accessory protein in the diet, particularly in the case of convalescents. Attempts to remedy the dietary deficiencies of gelatin by supplementing the diet with the missing amino acids have not been successful; the reason is not known. Gelatin gives a negative Hopkins-Cole test because it is lacking in tryptophan. The low content of tyrosine and cystine usually results in a negative or at the most a faintly positive reaction with Millon’s reagent and the lead-blackening test. The isoelectric point of gelatin is about pH 4.7.

EXPERIMENTS ON WHITE FIBROUS TISSUE

The tendo achillis of the ox may be taken as a satisfactory type of the white fibrous connective tissue.

<sup>7</sup> *J. Am. Med. Assoc.*, 150, 220 (1952).

**1. Preparation of Tendomucoid.** Dissect away the fascia from about the tendon and cut the clean tendon into small pieces. Wash the pieces in running water, subjecting them to pressure in order to remove as much as possible of the soluble protein and inorganic salts. This washing is very important. Transfer the washed pieces of tendon to a flask and add 300 ml. of half-saturated lime water. Shake the flask at intervals for 24 hours. Filter off the pieces of tendon and precipitate the mucoid with dilute hydrochloric acid. Allow the mucoid precipitate to settle, decant the supernatant fluid, and filter the remainder. Test the mucoid as follows:

- a. TEST FOR CYSTINE AND CYSTEINE SULFUR.
- b. HYDROLYSIS OF TENDOMUCOID. Place the remainder of the mucoid in a small beaker, add about 30 ml. of water and 2 ml. of dilute hydrochloric acid, and boil until the solution becomes dark brown. Cool the solution, neutralize it with concentrated sodium carbonate, and test by Benedict's test.

**2. Collagen.** This substance is present in the tendon to the extent of about 32 per cent. Therefore in making the following tests upon the pieces of tendon from which the mucoid, soluble protein, and inorganic salts were removed in the last experiment, we may consider the tests as being made upon collagen.

- a. BIURET TEST.
- b. XANTHOPROTEIC REACTION.
- c. GLYOXYLIC ACID REACTION (HOPKINS-COLE).
- d. TEST FOR CYSTINE AND CYSTEINE SULFUR. Take a large piece of collagen in a test tube and add about 5 ml. of sodium hydroxide solution. Heat until the collagen is partly decomposed, then add 1 to 2 drops of lead acetate and again heat to boiling.
- e. FORMATION OF GELATIN FROM COLLAGEN. Transfer the remainder of the pieces of collagen to a casserole, fill the vessel about two-thirds full of water, and boil for several hours, adding water at intervals as needed. By this means the collagen is transformed and gelatin is produced (see p. 245).

**3. Gelatin.** On the gelatin formed from the transformation of collagen in the above experiment (e), or on gelatin furnished by the instructor, make the following tests:

- a. MILLON'S REACTION.
- b. GLYOXYLIC ACID REACTION (HOPKINS-COLE).
- c. TEST FOR CYSTINE AND CYSTEINE SULFUR.

Make the following tests upon a solution of gelatin in hot water:

- a. COAGULATION TEST. Does it coagulate upon boiling?
- b. PRECIPITATION BY ALCOHOL. Fill a test tube one-half full of 95 per cent alcohol and pour in a small amount of concentrated gelatin solution. Do you get a precipitate? How would you prepare pure gelatin from the tendo achillis of the ox?

## II. YELLOW ELASTIC TISSUE (ELASTIN)

The ligamentum nuchae of the ox may be taken as a satisfactory type of the yellow elastic connective tissue. The principal solid constituent of this tissue is elastin, a member of the albuminoid group. In common with the keratins and collagen, elastin is an insoluble substance and gives the protein color reactions. It differs from keratin in amino acid composi-

tion and in the fact that it may be digested by proteolytic enzymes (see pp. 122 and 183–184). Elastin is characterized by its low sulfur content and its high content of leucine plus isoleucine.

Yellow elastic tissue also contains mucoid and collagen but these are present in much smaller amount than in white fibrous tissue, as may be seen from the following percentage composition<sup>8</sup> of the fresh ligamentum nuchae of the ox.

## EXPERIMENTS ON ELASTIN

**1. Preparation of Elastin (Richards and Gies).** Cut the ligament into fine strips, run it through a meat chopper, and wash the finely divided material in cold, running water for 24 to 48 hours. Add an excess of half-saturated lime water, and allow the hashed ligament to extract for 48 to 72 hours. Decant the lime water, remove all traces of alkali by washing in water, and then boil in water with repeated renewals until only traces of protein material can be detected in the wash water. Decant the fluid and boil the ligament in 10 per cent acetic acid for a few hours. Treat the pieces with 5 per cent hydrochloric acid at room temperature for a similar period, extract again in hot acetic acid and in cold hydrochloric acid. Wash out traces of acid by means of water and then thoroughly dehydrate by boiling alcohol and boiling ether in turn. Dry in an air bath and grind to a powder in a mortar.

**2. Xanthoproteic Reaction.**

**3. Biuret Test.**

**4. Glyoxylic Acid Reaction (Hopkins-Cole).**

**5. Test for Cystine and Cysteine Sulfur.**

## III. CARTILAGE

The principal solid constituents of the matrix of cartilaginous tissue are chondromucoid, chondroalbumoid, and collagen. Chondromucoid on decomposition yields protein and chondroitin sulfuric acid which has the following formula:

<sup>8</sup> Later experiments (Hall, Reed, and Tunbridge: *Nature*, **170**, 264 (1952)) show the presence of *elastomucin*, a carbohydrate-containing protein. The "elastin" of the earlier investigators was probably a mixture of elastin and elastomucin.

**Chondroitin sulfuric acid**

On hydrolysis it loses sulfuric acid and forms chondroitin. The latter loses acetic acid to form chondrosin. Chondrosin on hydrolysis yields chondrosamine  $\text{CH}_2\text{OH}(\text{CHOH})_3\text{CHNH}_2\text{CHO}$  and glucuronic acid  $\text{COOH}(\text{CHOH})_4\text{CHO}$ . Chondrosamine is apparently a galactosamine. The amino sugars are dealt with differently in metabolism from glucose or simple amino acids. They apparently do not form glycogen in the body. Chondromucoids in various tissues differ from each other in the character of the protein only. Chondroitin sulfuric acid differs from the sulfuric acids found in the mucin of saliva, etc., in that the carbohydrate group in the latter is chitosamine (probably a glucosamine). It is of interest that chitin in the exoskeleton of certain lower animals is a polysaccharide containing chitosamine and acetic acid. Chondroitin sulfuric acid is found in tendomucoid and apparently also in osseomucoid, which are thus closely related to chondromucoid.

It has been shown that a deposition of radioactivity in the knee-joint cartilage of young rats follows the administration of radioactive sulfur in the form of sulfate. This radioactivity was concentrated in the chondroitin sulfate (chondroitin sulfuric acid) fraction of the cartilage. Thiouracil and thyroxine influence the radioactivity pattern. For example, in animals pretreated with thiouracil the uptake of radioactive sulfur in the cartilage was reduced. The administration of thyroxine counteracted the action of thiouracil. It was further shown through the use of isotopes that 0.134 g. of chondroitin sulfate was formed per 100 g. of cartilage in 24 hours. The actual rate of sulfate formation was thus determined for the first time.

Chondroalbumoid is similar in some respects to elastin and keratin. It differs from keratin in being digestible by proteolytic enzymes and in containing considerably less sulfur than any member of the keratin group. It gives the usual protein color reactions.

## EXPERIMENTS ON CARTILAGE

**1. Preparation of Chondroitin Sulfuric Acid from Chondromucoid.** Free nasal septa of cattle from bone and other extraneous material. Run 200 g. of the material through a meat chopper. Add 400 ml. of 2 per cent NaOH. Let stand for 2 days. Strain through cloth. Treat the residue again with 200 ml. of NaOH for 2 days. Strain. Wash the residue once with water. Combine the extracts. Acidify with acetic acid and then add an excess of barium carbonate. Concentrate on the steam bath to half the volume. Pour off the clear liquid. Filter the remainder on a folded filter and add filtrate to the decanted solution. Acidify. Evaporate to about 80 ml. Centrifuge to remove protein and barium carbonate. Drop the clear yellow liquid into 8 volumes of glacial acetic acid kept vigorously agitated (preferably with a turbine). Filter off the acid potassium salt with suction. Wash with glacial acetic acid and then with alcohol and ether.

Dissolve 8 g. of the product which still gives a slight biuret test in 400 ml. of water, and while the solution is kept stirred drop in basic lead acetate solution to complete precipitation. Wash the precipitate several times by rubbing in a mortar with water and filtering with suction. Dissolve the precipitate in 10 per cent HCl. To the filtrate from the lead chloride add glacial acetic acid to precipitate all of the chondroitin sulfuric acid. Wash with glacial acetic acid, alcohol, and finally ether.

**2. To Show the Presence of Sulfuric Acid and of Reducing Sugars in Chondromucoid.** Treat 50 g. of cartilage from nasal septum of the ox or cartilage rings from trachea of the ox with 100 ml. of 1 per cent NaOH and let stand over night. Pour off 50 ml. of fluid, add 5 ml. of concentrated HCl and boil for 30 minutes, bringing down to a low volume. To one portion add  $\text{BaCl}_2$  solution and note the precipitate of  $\text{BaSO}_4$ . Neutralize another portion with sodium carbonate and apply Benedict's test to show the presence of a reducing carbohydrate group.

## OSSEOUS TISSUE (BONE)

Bone contains from 14 to 44 per cent water, depending upon the type of bone and its location in the body. Of the fat-free dry matter of bone, from 30 to 50 per cent is organic, and the remainder inorganic. Typical analyses of bone are given in Chapter 35 in connection with the discussion of rickets and vitamin D.

The organic portion of bone is similar in composition to cartilage. It contains collagen (*ossein*), osseoalbumoid, and osseomucoid. These proteins resemble the corresponding proteins in cartilage and tendon. Because of the collagen content, gelatin is formed when bone is boiled with dilute acid. The bone marrow also contains fat.

The inorganic material of bone consists chiefly of calcium, phosphate, and carbonate with small amounts of magnesium, sodium, strontium, lead, citrate, fluoride, hydroxide, and sulfate. These substances are present in amounts which correspond to 84 per cent  $\text{Ca}_3(\text{PO}_4)_2$ , 10 per cent  $\text{CaCO}_3$ , 2 per cent  $\text{Ca}_3(\text{citrate})_2$ , 1.0 per cent  $\text{Mg}_3(\text{PO}_4)_2$ , 1.0 per cent  $\text{MgCO}_3$ , and 2.0 per cent  $\text{Na}_2\text{HPO}_4$ . This composition is by no means constant. Wide variations have been encountered. For example, the molar proportions of  $\text{PO}_4:\text{CO}_3$  can be anywhere from 1.8 to 3.4. These changes in composition are related to changes in the  $\text{PO}_4:\text{CO}_3$  ratio of blood se-

rum. The composition of blood serum in turn is influenced by nutrition, age, and disease.<sup>9</sup> Despite the wide variations encountered in composition, x-ray diffraction studies reveal only one crystal structure, namely the *apatite lattice*. These hexagonal crystals in the bone are small in size, the

FIG. 69. MICROGRAPH OF CORTICAL BONE.

The diaphysis of a cat's femur autoclaved, agitated in blender, and subjected to ultrasonics. The two bacteria are *Bacillus aerogenes* and give an idea of the relative size of the crystals in relation to bacteria. Magnification 34,500.

Courtesy, R. A. Robinson and F. W. Bishop, and *Science*.

dimensions seen in the electron microscope being about  $500 \times 250 \times 100$  Ångstrom units (Fig. 69).

Because of this small size, the bone crystal offers a large surface that can adsorb other compounds than those which account for the crystal lattice itself. Evidence for this theory was the preferential solubility of carbonates and citrates in bone. There are many alternative theories, but the one which appears to be most acceptable is that of Hendricks, who visualizes the crystal structure of bone salts as due to hydroxyapatite

<sup>9</sup> Sobel, Rockenmacher, and Kramer: *J. Biol. Chem.*, 158, 475; and 159, 159 (1945).

$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ , in which F may replace OH, with the rest of the composition held by surface forces (Fig. 70).

Despite the possible variation in bone composition indicated in the discussion above, under some conditions the inorganic material of bone is rather constant in composition. Observations on the constancy of composition of bone during fasting are of interest in this connection. The

FIG. 70. SCHEMATIC INDICATIONS OF SURFACE COMPOUND FORMATION IN THE BONE SALT.

Courtesy, S. B. Hendricks, "Comments on Crystal Chemistry of Bone" from the Fourth Conference on Metabolic Interrelations of the Josiah Macy, Jr. Foundation.

percentage composition of the dry fat-free femurs of two dogs, after the animals had fasted for 104 and 14 days respectively, was as follows:

| Dog No. | Length of Fast | Ash  | N   | Ca   | Mg  | P    |
|---------|----------------|------|-----|------|-----|------|
| 1       | 104 days       | 61.5 | 4.6 | 23.3 | 0.5 | 12.8 |
| 2       | 14 days        | 61.7 | 4.1 | 23.2 | 0.5 | 12.9 |

The marked uniformity in composition notwithstanding the wide variation in the fasting periods is significant. The tensile strength of the femur of the dog has been found to be at least 25,000 pounds to the square inch whereas that of oak is 10,000 and that of cast iron 20,000 pounds to the square inch.

The percentage compositions of normal human bone and of bone from a case of osteomalacia with respect to certain elements are given in the following table:

| Constituent     | Kind of Bone |              |
|-----------------|--------------|--------------|
|                 | Normal       | Osteomalacia |
| Calcium.....    | 20.2         | 10.8         |
| Magnesium.....  | 0.1          | 0.3          |
| Phosphorus..... | 8.6          | 5.3          |
| Sulfur.....     | 0.1          | 0.6          |

Hammett has shown in the case of albino rats that there is an increase in calcium and a decrease in magnesium and phosphorus during the first 75 days of growth. Moreover the bones of the female have a higher calcium content than the bones of the male.

**Chemistry of Ossification.** Evidence from many sources indicates that there is an active metabolism in bone. The mineral matter of bone may be drawn upon in case of need elsewhere, as in the formation of milk by the lactating animal and in the formation of the bones of the fetus during pregnancy. This utilization of bone material should be regarded as a resorption of bone rather than a simple decalcification since both the organic and inorganic components of bone disappear during the process. Studies with radioactive phosphorus as a tracer<sup>10</sup> have shown that almost immediately after the introduction of radioactive phosphorus into the blood there is an appreciable uptake of the labeled phosphorus by the bones, indicating a turnover or metabolic interchange between the bone and plasma or lymph phosphorus. During a 50-day period in the life of the rabbit, for example, half the scapula may be replaced, with a 30 per cent turnover of the epiphyseal phosphorus; diaphyseal bone metabolism appears to be considerably slower. There are indications of a labile fraction of bone which is in equilibrium with the plasma and a stable fraction which is in equilibrium with the labile portion.

The mechanism of *calcification* is not clear. That the solubility-product principle operates is indicated from studies of healing rickets in vivo as well as in vitro. Not until the product of the ionic concentration of calcium and phosphate exceeds a minimum is there any new mineralization in the embryonic or rachitic bone cartilage matrix. This minimum is not the same for all bones, as is shown in the table below:<sup>11</sup>

THE SOLUBILITY-PRODUCT  
PRINCIPLE AND NEW  
CALCIFICATION

| Bone       | $Ca \times P^*$ |
|------------|-----------------|
| Embryonic  | 16              |
| Rachitic   | 35              |
| Be Rickets | 60              |
| Sr Rickets | 90              |

\* Minimum for new calcification in vitro; *Ca* and *P* are expressed as mg. per 100 ml. of solution; *P* represents inorganic phosphate.

<sup>10</sup> Hevesy: *Ann. Rev. Biochem.*, **9**, 641 (1940); Cohn, Cohn, and Aub: *Ann. Rev. Biochem.*, **11**, 415 (1942).  
<sup>11</sup> Sobel and Hanok: *J. Biol. Chem.*, **197**, 669 (1952).

Thus one must postulate the existence of local factors in the calcifying site whose concentration determines the level at which the solubility product operates. Several explanations have been offered for the nature of this local factor. Phosphatase, present in bone cartilage, has been suggested as the enzyme which on splitting organic phosphate causes supersaturation of calcium phosphate, thus promoting precipitation. It has also been suggested that glycogen and the enzymes responsible for phosphorylative glycogenolysis provide both the organic phosphate and the local mechanism. More recently, however, Sobel advanced the view that a mucopolysaccharide, chondroitin sulfate, is the local factor, based on (1) the presence of this compound at the site of mineralization; (2) the observation that when phosphatase and enzymes of the phosphorylative glycogenolysis are destroyed by heating and other measures, bone sections will still mineralize; (3) studies of the reversible inactivation of the ability of bone to calcify in vitro, by cations such as  $\text{Be}^{++}$  and  $\text{Cu}^{++}$  as inactivators and  $\text{Ca}^{++}$  as the reactivating ion.

Although the precipitate found in bone is composed of  $[\text{Ca}_3(\text{PO}_4)_2]_n \cdot \text{CaCO}_3$  ( $n = 1.8$  to  $3.4$ ), studies of the physicochemical mechanism indicate that the first aggregate formed is  $\text{CaHPO}_4$  which is rapidly transformed to hydroxyapatite. So far, however, no direct evidence has been found for the existence of  $\text{CaHPO}_4$  in bone.

Vitamin D promotes calcification, especially when added to rachitogenic diets. Under the influence of the antirachitic vitamin, the serum  $\text{Ca} \times \text{P}$  product becomes elevated as shown below:

INFLUENCE OF VITAMIN D ON SERUM CA AND P\*  
(Mean Values)

| Diet, per cent |      | Serum, mg. per cent |     |      |     |
|----------------|------|---------------------|-----|------|-----|
| Ca             | P    | Ca                  | P   | Ca†  | P†  |
| 1.20           | 0.12 | 11.7                | 2.1 | 13.3 | 3.4 |
| 0.19           | 0.12 | 9.4                 | 4.7 | 11.1 | 6.0 |
| 0.03           | 0.76 | 5.6                 | 7.5 | 8.8  | 8.4 |

\* 23-day-old rats on a rachitogenic diet for 30 days.

† Receiving 100 units of vitamin D daily.

P = inorganic phosphate.

This elevation in serum  $\text{Ca} \times \text{P}$  is probably the main reason for the effectiveness of vitamin D. In diseases like Fanconi's rickets in which this elevation of serum  $\text{Ca} \times \text{P}$  does not take place, the rachitic condition persists. Though the mode of action of vitamin D is not fully clear, there is both increase in the absorption of calcium from the intestinal tract and increased resorption of phosphate from the kidney. Both of these effects of vitamin D would tend to elevate serum  $\text{Ca} \times \text{P}$  and thus promote calcification. The finding of a high phosphatase content of the blood in osteitis deformans, rickets, and other generalized bone disorders, and a decrease of phosphatase in the tissues of the animals fed a diet high in vitamin D, are of interest in this connection. Calcium metabolism and

deposition are also influenced by the endocrine glands (see Chapter 26, Hormones).

## EXPERIMENTS ON OSSEOUS TISSUE

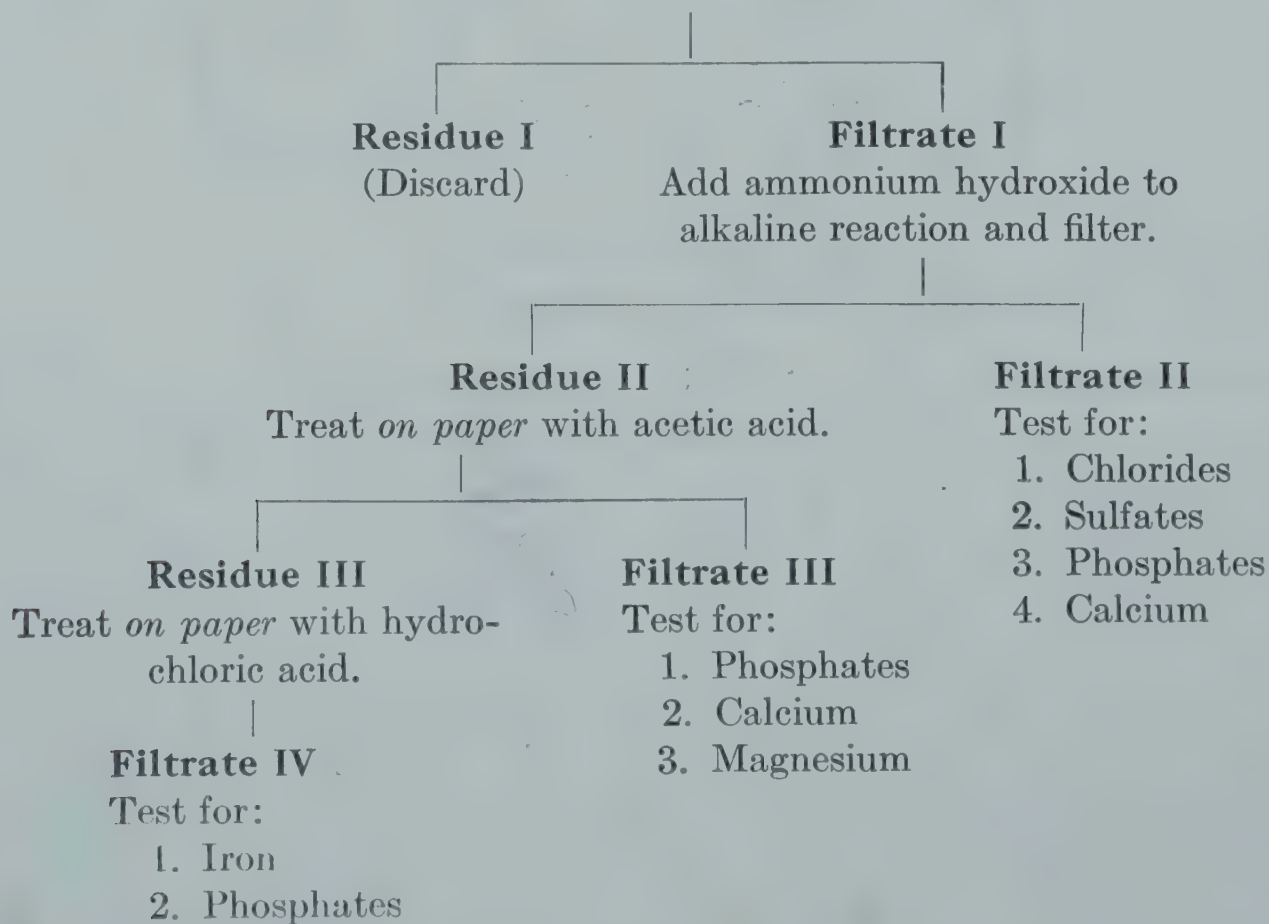

**1. Decalcification of Bone.** Treat a strip of rib bone with dilute  $\text{HNO}_3$  and permit it to soak for 6 to 8 days, renewing the acid every 1 to 2 days. After complete decalcification, wash the bone, split it, and remove the marrow. Now cut the bone into small pieces, wash it to remove acid, and boil the material in water for at least one hour. Filter, concentrate the filtrate, and permit it to cool. What is the characteristic of the cooled filtrate? What has been produced from the bone?

**2. Qualitative Analysis of Bone Ash.** Take 1 g. of bone ash in a small beaker and add a little dilute nitric acid. What does the effervescence indicate? Stir thoroughly, and when the major portion of the ash is dissolved add an equal volume of water and filter. To the acid filtrate add ammonium hydroxide to alkaline reaction. A heavy white precipitate of phosphates results. (What phosphates are precipitated here by the ammonia?) Filter and test the filtrate for chlorides, sulfates, phosphates, and calcium. Add dilute acetic acid to the precipitate on the paper and test a little of this filtrate for calcium and phosphates. Heat the remainder of the filtrate to boiling and add  $(\text{NH}_4)_2\text{CO}_3$  and  $\text{NH}_4\text{Cl}$  slowly to this hot solution as long as a precipitate forms. Filter off the precipitate of  $\text{CaCO}_3$  and wash with hot water until free from alkali.<sup>12</sup> To the filtrate add a solution of  $\text{Na}_2\text{HPO}_4$ , make strongly alkaline with  $\text{NH}_4\text{OH}$ , and note the formation of a white precipitate of ammonium magnesium phosphate ( $\text{NH}_4\text{MgPO}_4$ ). Examine the crystals under the microscope and compare with those shown in Fig. 226. To the precipitate on the filter paper, which was insoluble in acetic acid, add a little dilute hydrochloric acid and test this last filtrate for phosphates and iron.

Reference to the scheme below may facilitate the analysis.

### Bone Ash

Add dilute nitric acid, stir thoroughly, and after the major portion of the ash has been brought into solution, add a little distilled water and filter.

<sup>12</sup> Magnesium is not precipitated here because of presence of  $\text{NH}_4\text{Cl}$ .

MICROESTIMATION OF THE INORGANIC CONSTITUENTS OF BONE.<sup>13</sup> Sobel et al., have described a scheme for analysis of  $\text{CO}_3$ , Ca, P, and total base which is serial in operation and requires only one weighed specimen. The complete analysis can be performed on as little as 5 mg. of sample.

FIG. 71. SCHEMATIC DRAWING OF A TOOTH AND THE SURROUNDING STRUCTURE.

Courtesy, Zeisz and Nuckolls: *Dental Anatomy*, St. Louis, C. V. Mosby Co., 1949, p. 25.

## TEETH

**Composition.** Teeth are composed of four tissues: enamel, dentin, and cementum which are highly calcified, and the dental pulp which is uncalcified and is surrounded by the dentin (Fig. 71). Enamel covers the

<sup>13</sup> Sobel, Rockenmacher, and Kramer: *J. Biol. Chem.*, 152, 255 (1944).

dentin in the crown of the tooth. It is the hardest substance in the body and contains the smallest amount of water. Cementum contains about 30 per cent organic matter. It covers the dentin in the root of the tooth, which is contained in the supporting structures known as the periodontal tissues. These tissues, which include the gingiva and alveolar bone, hold the teeth in line. The periodontal membrane, which is adjacent to the cementum, connects the teeth to the gingiva and alveolar bone.

The average composition of human enamel and dentin is shown in the following table.

COMPOSITION OF HUMAN ENAMEL AND DENTIN

| <i>Constituent</i>              | <i>Enamel</i>                 | <i>Dentin</i> |
|---------------------------------|-------------------------------|---------------|
|                                 | <i>Per Cent on Dry Basis*</i> |               |
| Ash                             | 97                            | 72            |
| Calcium                         | 35.8                          | 26.5          |
| Magnesium                       | 0.4                           | 0.8           |
| Sodium                          | 0.7                           | 0.2           |
| Potassium                       | 0.3                           | 0.07          |
| Phosphorus                      | 17.4                          | 12.7          |
| Carbon dioxide (from carbonate) | 2.8                           | 3.06          |
| Chlorine                        | 0.3                           | 0.03          |
| Fluorine                        | 0.0112                        | 0.0204        |
| Iron                            | 0.0218                        | 0.0072        |
| Organic matter                  | 1                             | 20            |

\* Water which is not removed at about 100° C., the temperature to which the material is usually heated before analysis, was included in the weight from which calculations were made. The percentage of such combined water is approximately 2 for enamel and 8 for dentin.

The average values for the composition of whole human teeth are shown in the following table.

| <i>Whole Human Teeth</i>         |      |
|----------------------------------|------|
| <i>Constituents in Per Cent*</i> |      |
| Calcium                          | 29.7 |
| Magnesium                        | 0.6  |
| Phosphorus                       | 14.2 |
| Carbon dioxide (from carbonate)  | 2.9  |
| Water                            | 8.7  |
| Inorganic matter                 | 84.7 |
| Organic matter                   | 15.3 |

\* Data of Lefevre and Hodge: *J. Dental Research*, 16, 279 (1937) and Crowell, Hodge, and Line: *J. Dental Research*, 14, 251 (1934), recalculated. The value for water represents the loss in weight after heating the teeth at 96° C. for seven days. The weight after this treatment is the dry weight. The values for inorganic and organic matter, and the values for calcium, magnesium, phosphorus, and carbon dioxide represent the percentages of the dry weight (weight on dry basis).

On the basis of chemical analysis, it was thought at one time that most of the calcium and phosphorus in the dental tissues existed as  $\text{Ca}_3(\text{PO}_4)_2$ , a view formerly held also for bone. However, x-ray crystallographic studies suggest that the crystal structure of most of the calcium phosphate in the dental tissues is similar to that of hydroxyapatite,  $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ . The striking similarity of x-ray diffraction photographs of hydroxyapatite and enamel is shown in Fig. 72, which contains also the photographs of fluoapatite and chloroapatite. There is some evidence<sup>14</sup> which suggests that in the case of dentin and cementum additional phosphorus in the form of either  $\text{PO}_4^{=}$  or  $\text{HPO}_4^{=}$  or some other ion involving phosphorus is occluded in the hydroxyapatite molecule. The apatite salt

FIG. 72. X-RAY-DIFFRACTION PHOTOGRAPHS.

(a) Human dental enamel, (b) hydroxyapatite, (c) fluoapatite, (d) chloroapatite.

From Thewlis, Glock, and Murray: *Trans. Faraday Soc.* 35, 358 (1939).

known as tricalcium phosphate hydrate, which has been claimed by some to be the main inorganic salt in dentin and cementum, is probably hydroxyapatite with occluded phosphate ion. It is claimed that smaller amounts of carbonateapatite, chloroapatite, and fluoapatite are present in enamel, and that dentin contains some fluoapatite. A portion of the sodium, potassium, and magnesium in the dental tissues may be part of the apatite lattice by substitution for part of the calcium. Enamel and dentin on spectrographic examination have been found to contain numerous trace elements, including aluminum, barium, boron, chromium, copper, lead, lithium, manganese, nickel, silicon, silver, strontium, tin, titanium, vanadium, and zinc.

The electron microscope as well as x-ray studies reveal that the crystals of enamel are larger than those of bone or dentine.

The composition of growing teeth can be influenced in a predictable manner, high-carbonate teeth being produced on a high-calcium, low-phosphate diet and low-carbonate teeth on a low-calcium, high-phosphate diet.<sup>15</sup> Evidence to date indicates that high-carbonate teeth are more susceptible to caries.<sup>16</sup>

<sup>14</sup> Posner and Stephenson: *J. Dental Research*, 31, 371 (1952).

<sup>15</sup> Sobel and Hanok: *J. Biol. Chem.*, 176, 1103 (1948).

<sup>16</sup> Sobel: *Fourth Josiah Macy Conference on Metabolic Interrelations*, 1952, p. 261.

The organic matter of enamel consists mainly of the protein keratin, which on the basis of the proportion of histidine, lysine, and arginine is of eukeratin nature (see p. 184). Small amounts of cholesterol and phospholipide are also present. The albuminoids collagen and elastin are found in dentin, collagen representing the major organic constituent of this tissue. Glycoprotein is present in dentin along with small amounts of cholesterol and phospholipide. Collagen is the main organic constituent of cementum. Citrate has been identified as a constituent of human teeth, five to eight times more being present in dentin than in enamel.

CHRONOLOGY OF HUMAN DENTITION  
(Logan and Kronfeld, slightly modified by McCall and Schour)

| <i>Tooth</i>           |                 | <i>First evidence<br/>of calcification</i> | <i>Enamel<br/>completed</i> | <i>Root<br/>completed</i> |            |
|------------------------|-----------------|--------------------------------------------|-----------------------------|---------------------------|------------|
| Deciduous<br>dentition | Central incisor | 4 mos. in utero                            | 4 mos.                      | 1½–2 yrs.                 |            |
|                        | Lateral incisor | 4½ mos. in utero                           | 5 mos.                      | 1½–2 yrs.                 |            |
|                        | Cuspid          | 5 mos. in utero                            | 9 mos.                      | 2½–3 yrs.                 |            |
|                        | First molar     | 5 mos. in utero                            | 6 mos.                      | 2–2½ yrs.                 |            |
|                        | Second molar    | 6 mos. in utero                            | 10–12 mos.                  | 3 yrs.                    |            |
| Permanent<br>dentition | Upper<br>jaw    | Central incisor                            | 3–4 mos.                    | 4–5 yrs.                  | 10 yrs.    |
|                        |                 | Lateral incisor                            | 1 yr.                       | 4–5 yrs.                  | 11 yrs.    |
|                        |                 | Cuspid                                     | 4–5 mos.                    | 6–7 yrs.                  | 13–15 yrs. |
|                        |                 | First bicuspid                             | 1½–1¾ yrs.                  | 5–6 yrs.                  | 12–13 yrs. |
|                        |                 | Second bicuspid                            | 2–2¼ yrs.                   | 6–7 yrs.                  | 12–14 yrs. |
|                        |                 | First molar                                | At birth                    | 2½–3 yrs.                 | 9–10 yrs.  |
|                        |                 | Second molar                               | 2½–3 yrs.                   | 7–8 yrs.                  | 14–16 yrs. |
|                        |                 | Third molar                                | 7–9 yrs.                    | 12–16 yrs.                | 18–25 yrs. |

Several investigations have been made in an attempt to ascertain whether differences in chemical composition exist between enamel of sound teeth and the intact enamel of carious teeth. No significant differences were found for the contents of calcium, magnesium, phosphorus, and carbonate. Similar studies on dentin have likewise given negative results. On the other hand, it has been reported<sup>17</sup> that enamel from sound teeth contains significantly more fluorine than does the sound enamel from carious teeth, although no difference was found for dentin. However,

<sup>17</sup> Armstrong and Brekhus: *J. Dental Research*, 17. 393 (1938).

this difference between sound and carious teeth was not found in all localities where these determinations were made.<sup>18</sup> (See p. 262 for additional data on the relationship of fluorine and teeth.) No difference was found in the ash, calcium, and phosphorus contents of the root dentin of teeth from pregnant and nonpregnant women; this fact suggests that there is no basis for the view that minerals are withdrawn from the teeth during pregnancy. Furthermore, clinical investigation has shown that the incidence of dental decay in pregnant women is no greater than in nonpregnant women of corresponding age.

**Chronology of Dentition.** The ages at which the deciduous and permanent teeth begin to calcify and are completed are shown in the table<sup>19</sup> on p. 258.

In a study of calcification of teeth at birth, it was found that all the teeth of both jaws contained approximately 212 mg. of calcium and 106 mg. of phosphorus. At the time of birth the lateral incisors, the cuspids, the first deciduous molars, the second deciduous molars, and the first permanent molars contained respectively 20, 7.5, 21, 11, and 0.1 per cent of the calcium present in the fully erupted teeth. These data thus indicate that the postnatal period is of far greater importance than the prenatal period in the calcification of the deciduous as well as of the permanent teeth.

### SYSTEMIC EFFECTS

In studies dealing with the response of the dental tissues to systemic influences it is important to distinguish between the developing and the adult teeth, and between the dental tissues of limited growth, as in humans, and those of continuous growth like the incisors of rats. A great deal of confusion has been caused by failure to recognize this distinction.

Adult teeth of limited growth are probably only slightly affected by systemic influences. That such effects may occur is suggested by studies in which radioactive isotopes have been used. For example, it was shown that following the ingestion or injection of sodium phosphate containing radioactive phosphorus, small amounts of the isotope appeared in the enamel and dentin, but much smaller amounts were present in the former than in the latter. However, the slight extent to which this occurs is shown by the fact that after the ingestion of 900 mg. of sodium phosphate containing isotopic P by an individual twenty-five years of age, about 1/300,000 of the labeled P entered a single tooth. On the basis of such data it was calculated that the replacement of 1 per cent of the total tooth phosphorus by that taken up in food would take about 250 days.

For the proper calcification of the teeth the diet must contain adequate quantities of calcium and phosphorus and certain vitamins. Some of the hormones likewise play a fundamental role.

**Vitamins, Calcium, and Phosphorus.** The presence of vitamin A is essential to the process of tooth formation. Dietary deficiency of this vitamin during the period that the teeth are undergoing development

<sup>18</sup> McClure: *J. Dental Research*, 27, 287 (1948).

<sup>19</sup> Logan and Kronfeld: *Histopathology of the Teeth and Their Surrounding Structures*, revised and re-edited by Boyle, Philadelphia, Lea & Febiger, 1949, p. 41.

causes the ameloblasts (enamel-forming cells) to atrophy, resulting in hypoplastic (incompletely developed) enamel which is imperfectly calcified. There is also atrophy of the odontoblasts (dentin-forming cells) so that the dentin laid down is also incompletely calcified. It is claimed that the primary effect is on the enamel, irregularities in the development of the dentin being secondary to the enamel hypoplasia. Deficiency of vitamin A in rats has been found to produce an increase in the percentage of magnesium in the incisors in spite of the fact that the ash content is decreased. A characteristic effect of vitamin A deficiency—namely, the substitution of stratified keratinizing epithelium for normal epithelium—has been observed in the gingiva. Malformation of alveolar bone has been produced in dogs by feeding them vitamin A-deficient diets.

Vitamin C is also important for the functional activity of the formative cells. Dietary deficiency in vitamin C during the period of tooth development causes impairment of the odontoblasts, leading to defective calcification of the dentin accompanied by hemorrhagic and degenerative lesions in the pulp tissue. The changes in the dentin and pulp have been attributed to an inability to produce and maintain intercellular substance. Defective enamel formation, which has also been observed, is said to be secondary to retarded dentin deposition. Pathological changes in gingival tissue have been demonstrated to be due to deficiency of vitamin C in the diet. These conditions, as well as those in the teeth themselves, have been shown to respond favorably to the addition to the diet of vitamin C.

The degree of mineralization of the teeth depends on the relative as well as on the absolute quantities of calcium and phosphorus in the diet, and also on the amount of vitamin D or exposure to ultraviolet rays. Even with optimal quantities of calcium and phosphorus the presence of vitamin D is essential to the development of perfect teeth. Hypoplastic defects in the enamel and imperfect calcification of the dentin have been found in rickets in children. It has been reported that an increase in the vitamin D intake brings about a reduction in the incidence of dental decay in children. Similar results have been produced in rats by adding vitamin D to a caries-producing diet.

Although both teeth and bones are highly calcified tissues, metabolic effects in the one do not necessarily parallel those in the other. For example, although the percentage of ash of the incisor teeth of rats fed a low-calcium, low-phosphorus diet was lower than that of animals on a normal diet, the absolute amount of ash on the deficient diet increased about 15 per cent during a period of nine weeks. In the normal animals there was an increase of 77 per cent. But during this period there was a reduction of 16 per cent in the absolute amount of ash in the femurs of the animals on the deficient diet, while in the normal animals there was an increase of 38 per cent. Thus there was a continuous deposition of minerals in the incisors of the rats on the deficient diet, while bone underwent demineralization. Furthermore, although the percentage of ash, calcium, and phosphorus of the tibiae of rats may be reduced to about the same extent on a high-calcium, low-phosphorus rachitic diet, and on a low-calcium, high-phosphorus rachitic diet, the values for these constit-

uents are unaffected in the incisors of the rats on the high-calcium diet, but are somewhat reduced on the low-calcium diet. These facts indicate that in some fundamental way there is a marked difference between the mineral metabolism of teeth and bones.

**Hormones.** Normal tooth growth requires an adequate supply of thyroxine. Hypothyroidism in children causes retardation in dental development although no structural defects of the teeth have been detected in this condition. (Structural defects and impaired calcification have, however, been found after thyroidectomy in monkeys and rabbits.) Reduced activity in the thyroid gland during morphodifferentiation, that is, in utero or in the first year of life, results in a reduction of the size and an alteration in the form of the crowns of the teeth. The size and form of the root may be altered by disturbances in the thyroid gland in later periods. In *hypothyroidism* there is delayed resorption and shedding of the deciduous teeth, whereas in *hyperthyroidism*, which is relatively rare in children, there is early shedding of the deciduous teeth and accelerated dentition.

Deficient parathyroid function may interfere with calcium and phosphorus metabolism to such an extent that growing teeth fail to calcify properly. If this occurs in infancy, enamel hypoplasia and disturbances in the calcification of dentin occur in the tissues calcifying at that time. In experimental hypoparathyroidism in rats, the incisor teeth, which grow throughout life in this animal, become brittle and distorted, whereas fully formed enamel and dentin show no changes. Administration of parathormone to parathyroidectomized rats results in normal calcification of the enamel and dentin calcifying during the period of treatment, but does not restore to normal the structures that were formed in the absence of parathyroid function. In hyperparathyroidism, although calcium and phosphorus are withdrawn from bone, there is no such withdrawal from the teeth. The teeth may become loose as a result of resorption of alveolar bone, but the teeth remain well calcified in spite of the severe drain upon bone.

The pituitary gland plays an important part in the rate of development of the teeth. Dysfunction of this gland usually does not occur before 4 to 6 years of age, that is, before the crowns of the permanent teeth (except the second and third molars) are fully formed. Since eruption of the teeth is retarded, the clinical crown may be smaller than normal. However, the size of the anatomic crown is not affected. Juvenile dental characteristics persist as shown by large pulps and incompletely developed roots. Disturbances occur in the calcification of the dentin and alveolar bone. One of the main dental effects in *hyperpituitarism* is an acceleration in the rate of eruption of the teeth.

In experimental hypogonadism in the male rat, evidence of disturbed calcification was apparent 60 to 90 days after castration. The male hormone therefore appears to have an effect on the calcification of teeth. In hypergonadism in humans, growth, calcification, and eruption of the teeth are accelerated, but not to the same extent as is skeletal growth.

Disturbances of the calcification of growing dentin have been reported in experimental adrenalectomy in the rat.

## FLUORINE AND TEETH

The mass occurrence of a characteristic dental defect known as mottled enamel or dental fluorosis was observed about 1908 in the inhabitants of Colorado Springs. Approximately 80 per cent of those who were born and raised in this community were affected to some degree. Those who came to the locality after their teeth had been completely formed were not afflicted with mottled enamel after residence there. Surveys of other communities revealed a similar dental defect. Analysis of the water in the communities where mottled enamel was found revealed the presence of excessive amounts of fluoride. At Bauxite, Arkansas, for example, the fluoride content of the water was 13 to 14 parts per million (13 to 14 mg. per liter), a condition which was subsequently remedied.

Enamel fluorosis is limited to children in whom the enamel of the permanent teeth has not been completed. Enamel formation is completed, except for the third molar, during the seventh to eighth year. It is completed in the third molars between the twelfth and sixteenth years. The disease is characterized by chalky white patches distributed over the enamel, which is pitted and corroded in extreme cases, resulting in loss of the normal translucency. The fluorine content of mottled enamel may be two to three times that of normal enamel; the fluorine content of dentine is likewise increased when water containing excessive amounts of fluoride is ingested during infancy and childhood.

It was found that in communities where dental fluorosis existed there was less dental decay than in comparable communities where the water was practically fluoride-free. In one town where the water supply contained 1.8 parts of fluoride per million parts of water, there was about one-third as much dental decay as in a comparable group of children in another town where the water was almost fluoride-free. About 50 per cent of the children who were raised in the former community showed a mild dental fluorosis. On the basis of this early evidence and subsequent studies, many cities and towns are now adding fluoride to the water supply in an effort to reduce the incidence of dental caries. Fluoride is added to bring the concentration up to approximately 1 part per million, a level at which dental fluorosis is avoided. From the favorable reports regarding reduction of dental caries following this procedure, the addition of fluoride to water to the level of 1 part per million appears to be a worthwhile public health measure.

Another effort to reduce dental decay has involved topical application (application directly to the teeth) of from 0.1 to 2 per cent solutions of sodium or potassium fluoride. According to several reports<sup>20</sup> the incidence of dental caries has been materially reduced by this procedure; other reports have been negative. However, the evidence in favor of topical application of fluoride solutions appears to outweigh that against it. In this connection it is of interest to note that topical application of a 2 per cent sodium fluoride solution to the teeth of dogs has been found to increase

the fluoride content of the teeth to a significant degree.<sup>21</sup> Furthermore, enamel which has been treated with fluoride solutions is less soluble in acid than untreated enamel,<sup>22</sup> a fact of importance because in the process of dental decay, the mineral salts of enamel, and later of the dentin, are dissolved by acids which form as a result of the action of enzymes on carbohydrate.

## EXPERIMENTS ON TEETH

**Analysis of Teeth.** Place a tooth in 25 ml. of dilute nitric acid and allow to stand over night. On the solution obtained run an analysis for inorganic elements according to the procedure given for bone ash (p. 254). Separate analyses may be made on dentin and enamel. Note the very slight amount of organic matter in enamel.

**Quantitative Analysis of Teeth.** Weigh a clean dry tooth on an analytical balance. Put in a beaker, add 25 ml. of dilute HCl, and let stand over night. Dilute to exactly 100 ml. and filter.

**Determination of Calcium.** Pipet 10-ml. portions of tooth solution into each of two 250-ml. beakers. Add to each 20 ml. of 2.5 per cent oxalic acid solution, 2 drops of methyl red (saturated alcoholic solution), about 70 ml. of distilled water, and then concentrated  $\text{NH}_4\text{OH}$  drop by drop with vigorous stirring. When a precipitate of calcium oxalate begins to form add more ammonia very slowly until the color changes to an intermediate color between red and yellow. Let stand over night. Complete the determination according to directions in Chapter 31. Calculate the percentage of Ca in the tooth.

**Determination of Phosphorus.** Pipet 10 ml. of tooth solution into a 150-ml. beaker, add 2 drops of phenolphthalein solution and NaOH until the color just turns faint pink. Carry out a uranium acetate titration or determine colorimetrically according to the directions given in Chapter 31. Calculate the percentage of P.

# 10

## Muscular Tissue

### COMPOSITION OF MUSCLE

Muscular tissue constitutes about 40 per cent of the body weight, and is, therefore, the largest single tissue component of the body. There is great variability in the physiological and finer morphological characteristics of individual muscles, but it is usual to classify them as striated (skeletal, voluntary), cardiac, and smooth muscles. Chemically, striated muscle has been investigated more extensively than cardiac and, especially, smooth muscle.

In round numbers, striated muscle consists of 75 per cent water, 20 per cent proteins, and 5 per cent other solids, such as inorganic salts and the so-called "extractives."

### EXTRACTIVES OF MUSCLE

Under the name *extractives* are classed a number of muscle constituents which occur in small amounts in the tissue and may be extracted by water, alcohol, or ether. There are two classes of these extractives, the *non-nitrogenous* and the *nitrogenous*. Grouped under the non-nitrogenous compounds are glycogen, hexosephosphates, lactic acid, inositol, and fat. In the class of nitrogenous extractives are creatine phosphate, purine bases (xanthine, hypoxanthine), uric acid, adenylic acid, inosinic acid, carnosine (ignotine), anserine, and carnitine (novaine). All of these substances, and many more, have been obtained from dead muscle; there is evidence that some of them are produced largely by post-mortem reactions and are not present as such in significant amounts in living muscle. Other extractives besides those enumerated above have been described, and there are undoubtedly still others whose presence remains undetermined. A detailed consideration would, however, be unprofitable in this place.

### NON-NITROGENOUS EXTRACTIVES

**Lipides.** Like most organs, muscles contain storage fat (not dissimilar to that in other depots) as well as essential lipides. Phospholipides predominate among the latter. It has been estimated that mammalian muscles contain on the average 4.5 per cent phospholipides and 0.25 per cent cholesterol, in terms of dry weight. For the heart, these proportions are 7.5 and 0.5 per cent, and for smooth muscle 3 and 0.75 per cent, respectively (Bloor).

**Glycogen.** The chief carbohydrate of muscle is the polysaccharide glycogen (see p. 87). It may be prepared from muscle or other tissue by

extraction with boiling water followed by precipitation with alcohol. By such methods, opalescent solutions of amorphous glycogen are obtained, but by more careful procedures it can be shown that in the living tissue, glycogen occurs in the form of submicroscopic granules, comparable perhaps to vegetable starch grains, although much smaller.

The glycogen content of muscle varies and is reduced by intense activity, but is not, as is liver glycogen, significantly depleted as a result of a demand for carbohydrate elsewhere in the body. Glycogen occurs also in the heart; its behavior in this organ is not the same as in skeletal muscle, and requires further study.

**Hexosephosphates.** Of the several existing hexosephosphates, resting muscle contains only the so-called Embden ester. This is an equilibrium mixture of glucose-6-phosphate and fructose-6-phosphate (see p. 273), the only intermediates of the glycolytic cycle which accumulate to an appreciable extent under normal conditions.

**Inositol** occurs in muscle as it does in many tissues, but its mode of combination and its function are unknown (see Chapter 35).

**Lactic Acid.** This substance occurs in muscle in variable quantity, dependent on the physiological state of the organ. Resting muscle, after careful extraction, contains only very small amounts of lactic acid (e.g., 0.015 per cent in frog muscle) but it is found in larger amount after stimulation, in anaerobiosis, and post mortem. Rigor mortis is associated with lactic acid production and with depletion of adenosinetriphosphate.

## NITROGENOUS EXTRACTIVES

**Creatine.** Creatine, methylguanidinoacetic acid, is found in varying

amounts in muscles of vertebrates, frequently representing about 0.3 to 0.5 per cent of the wet tissue. The creatine of the body is maintained by synthesis of glycocyamine and its methylation, and a regular excretion of creatine takes place in the form of its anhydride, creatinine, in the urine, dependent somehow on the development of the muscular tissue. In muscular dystrophies, whether spontaneous as in man, or induced in animals by vitamin E deficiency, this creatine excretion is greatly enhanced.

Creatine forms colorless monoclinic prisms which are tasteless to some individuals but bitter to others, and which decompose with marked effervescence at about 291° C. (corr.). It is soluble in warm water and practically insoluble in alcohol and ether. Upon boiling a solution of creatine with dilute hydrochloric acid, it loses water and its anhydride, creatinine, is formed.

**Phosphocreatine.** Though creatine is present in meat extracts and may also be found in muscle after considerable activity, most of it does not exist as such in perfectly relaxed muscle, but occurs here as phosphocreatine, frequently about 2 millimoles per 100 g. The discovery of

Phosphocreatine

phosphocreatine was preceded by the observation that part of the apparent inorganic phosphate in muscle was in reality present as a labile compound, called phosphagen, which was hydrolyzed by molybdic acid under the conditions of the phosphate determination. This phosphagen was then identified as phosphocreatine by Fiske and SubbaRow. In in-

FIG. 73. CREATINE.

vertebrate animals, other phosphagens occur; among these, phospho-arginine has been shown to be of widespread occurrence.

**Purine Bases and Nucleotides.**<sup>1</sup> The purine bases occurring in muscle are adenine, guanine, xanthine, and hypoxanthine (for formulas see Chapter 7). These may exist in the form of nucleic acids and of mono- and oligonucleotides and their breakdown products. Among these, we shall discuss only the adenosine polyphosphates.

In all cases, the basic structure is adenosine, adenine-9-riboside; D(-)-ribose being the carbohydrate moiety. This is esterified with phosphoric acid at the 5 position of the ribofuranose, to form adenosine-5-phosphoric acid, also known as adenosinemonophosphate (AMP) or as muscle- or myoadenylic acid. Inosinic acid is a commonly occurring breakdown product of AMP, formed by deamination in muscle extract. Though the nature of adenylic deaminase has not been exhaustively investigated, it appears that myosin, even after considerable purification, displays such enzymic activity.

By attaching further phosphoric acid residues in pyrophosphate linkage, adenosinediphosphate (ADP) and adenosinetriphosphate (ATP) are obtained. In resting muscle as well as in the mammalian heart, ATP is

Adenosinetriphosphate

Adenosinediphosphate

Adenylic acid

Inosinic acid

the predominant form of the adenosine polyphosphates, usually in a concentration of about 0.5 millimole per 100 g.

**Carnosine.** This substance is a dipeptide of histidine and the amino acid  $\beta$ -alanine, which occurs also in pantothenic acid (see p. 35). Carnosine, often accompanied by anserine (methylcarnosine), is of widespread

Carnosine

occurrence in vertebrate muscle, but its function is not known.<sup>2</sup>

<sup>2</sup> du Vigneaud and Behrens: *Ergebn. Physiol.*, **41**, 917 (1939).

**Carnitine** is a betaine which gives trimethylamine on hydrolysis. Its

function in muscle is not known.

**Glutamine.** Skeletal and, particularly, cardiac muscle contain this substance in higher concentration than other mammalian tissues,<sup>3</sup> about 0.1 per cent. Its function is not known, but reference may be made to the discovery by Krebs<sup>4</sup> that glutamine is essential for the maintenance of the intracellular potassium in brain. (For formula of glutamine, see p. 145.)

INORGANIC SALTS

The predominating inorganic cation of muscle is potassium, occurring in a concentration of about 0.11 molar. It is accompanied by sodium, which, like the chloride ion, is mostly present in the tissue spaces rather than intracellularly. Also significant are calcium and magnesium (about 0.003 and 0.01 molar), which act as activators or inhibitors for many of the enzymes present. These positive ions act in part as counterions for the negatively charged proteins, and are, for the remainder, paired with various phosphoric esters and other anions. Free phosphate occurs, but is easily overestimated due to the lability of phosphocreatine. The actual estimates differ for different muscles, but the results of Hastings for rat muscle may be taken as representative for mammalian muscle.<sup>5</sup>

APPROXIMATE COMPOSITION OF 1 KG. OF MAMMALIAN MUSCLE

|                               | Grams | Milliequivalents |        | Distribution, per cent |               |

PROTEINS OF MUSCLE

The protein composition of muscle must be discussed in relation to the microscopic structure of this tissue. We can divide the proteins into those

<sup>3</sup> Archibald: *Chem. Revs.*, **37**, 162 (1945).

<sup>4</sup> Turner, Eggleston, and Krebs: *Biochem. J.*, **37**, 139 (1950).

<sup>5</sup> Hastings, in Najjar: *A Symposium on the Clinical and Biochemical Aspects of Carbohydrate Utilization in Health and Disease*, Baltimore, The Johns Hopkins Press, 1952

that are constituents of the fibrils and those that occur in the sarcoplasm, even if in practice it may not always be possible to make this distinction with certainty.

**Stroma.** About 20 per cent of the muscle protein cannot be dissolved with any known solvent short of strong urea or alkali solution. This fraction is commonly called stroma, and may consist, in part, of constituents of cell nuclei and connective tissue, including perhaps the sarcolemmal sheaths.

**Proteins of the Sarcoplasm.** If a muscle is perfused to remove blood, and is then minced and subjected to high pressure, a press juice is obtained which contains about one-fifth of the protein of the minced muscle. This press juice is probably derived from the sarcoplasm. Its main proteins were formerly called myogen and globulin X (Weber); the latter protein has not received further attention. *Myogen* is now recognized as a collective name for a number of water-soluble proteins, and it is probable that this fraction is made up entirely of various enzymes.<sup>6</sup>

In more complete yield, the proteins of the myogen group can be obtained by extracting minced muscle with water or dilute salt solutions (e.g., 0.15 molar KCl). It is then found that about 30 per cent of the muscle protein is contained in this fraction. Such extracts have been analyzed with the aid of electrophoresis, and this method too has shown the complexity of the so-called myogen (Dubuisson).

**Myoglobin.** A water-soluble protein which deserves separate mention is myoglobin. This protein is similar to hemoglobin (notwithstanding differences in molecular weight (17,000) and other properties) in that it is a heme protein which combines reversibly with oxygen. Its affinity for O<sub>2</sub> is higher than that of hemoglobin, so that the intracellular pigment may be fully oxygenated at O<sub>2</sub> tensions which cause unloading of the blood pigment. The distribution of myoglobin between white and red muscle has most interesting features correlated with physiological differences between the muscles. It may be said, in general, that myoglobin acts as a store of oxygen, although the functional meaning of this is not always clear.

Myoglobin can be released from muscles after crushing injury; because of the small size of the molecule, it is filterable through the renal glomeruli, and appears in the urine.

**Proteins of the Fibrils.** The two previous categories constitute nearly half of the muscle protein; the remaining half will now be discussed in detail. This fraction, which corresponds to the protein constituents of the fibrils, can be extracted with concentrated salt solutions (e.g., 0.5 M KCl), and has been extensively investigated.

**Myosin.** When relaxed skeletal muscle is minced and immediately extracted with 0.5 M KCl for an arbitrary length of time at neutral or weakly alkaline reaction, it is found that the extract, in addition to the soluble sarcoplasm proteins, contains a protein, called *myosin*, which can be precipitated by five fold to ten fold dilution of the extract, and can be redissolved in 0.5 M KCl. Myosin solutions thus obtained are distin-

---

<sup>6</sup> Herbert, Gordon, Subrahmanyam, and Green: *Biochem. J.*, **34**, 1108 (1940).

guished by a high viscosity and *flow birefringence*,<sup>7</sup> but these properties are found to be variable and are largely determined by the duration of the extraction; prolonged extraction gives rise to a *myosin* with higher viscosity and more intense birefringence of flow.<sup>8</sup>

**Actin.** Further analysis has shown that these phenomena are due to the combination of myosin with a new protein, *actin*,<sup>9</sup> to form the complex, *actomyosin*. This combination takes place in later stages of the extraction as soon as the adenosinetriphosphate in the system is decomposed; but the release of actin is also promoted by very fine mincing. Pure, actin-free myosin has been prepared in crystalline form by Szent-Györgyi. Its viscosity is moderate, and it shows no flow birefringence when tested with simple methods of observation. Upon combination with actin, however, the viscosity increases greatly, and flow birefringence is pronounced.

Actin can occur in two forms, called globular (G) and fibrous (F) actin. The former can be obtained by extracting acetone-dried muscle powder with water. After addition of salt, the G-F transformation takes place, as evidenced by an enormous increase in viscosity and the development of a strong flow birefringence.<sup>9</sup> These phenomena are ascribed to a suppression of molecular charges by the salt, whereupon the individual molecules unite to form long molecular strands.<sup>10</sup> Only F-actin forms an actomyosin with the described characteristics.

Both actin and myosin are now available as apparently pure proteins. For myosin, purity is achieved by carefully controlled precipitation procedures. The molecular weight of myosin has been difficult to determine, owing to anomalies in its behavior, but is now found to be 600,000, the molecule apparently being a rod 1500 Å long.<sup>11</sup> Actin has been purified by fractional ultracentrifugation of F-actin, followed by careful depolymerization to G-actin; the molecular weight is about 57,000.<sup>12</sup>

Much remains to be elucidated about the exact state in which these proteins occur in the muscle fibril. Electron microscopy has shown, however, that long filaments, presumably actomyosin, run along the fibrils, and that other substances are spaced in a regular fashion, corresponding to the microscopically visible cross striations and other structural details.<sup>13</sup>

**Tropomyosin.** This protein was crystallized by Bailey after extraction from alcohol-dried muscle. Its behavior is opposite to that of actin in that it is aggregated in the absence of salt, but has its flow birefringence abolished by salt. However, it is not known to be related to contractile phenomena.

There is a good deal of similarity in amino acid composition between myosin, tropomyosin, and actin. Apparently, these proteins are built on another pattern than seed, egg, or blood proteins.

## BIOCHEMISTRY OF MUSCULAR ACTIVITY

Our present knowledge of the chemistry of muscular contraction is based upon the intensive studies of many investigators over a long period of time. Perhaps no other single phase of animal biochemistry has so persistently attracted the attention of so many biochemists and physiologists. Muscles from both warm- and cold-blooded animals have been studied; skeletal, cardiac, and (to a lesser extent) smooth muscles have been used; and studies have been carried out on the isolated intact muscle, muscle extracts, and enzyme systems obtainable from these extracts. The discussion which follows is a summary of present knowledge, necessarily incomplete and subject to future revision, concerning the chemical processes associated with muscle contraction.

### GLYCOLYSIS

Glycolysis is the preponderant metabolic process in muscle under anaerobic conditions, but may also occur aerobically in those muscles which do not contain enough oxidative enzymes to fulfill the metabolic requirements of increased activity. In the human body, considerable amounts of lactic acid appear in strenuous exercise; much of this lactic acid is reconverted to glycogen by the liver.

**Glycogenolysis.** Breakdown of glycogen can be effected hydrolytically by *amylase*, but this occurs in digestion rather than in tissue metabolism. In muscle and other organs, the breakdown is phosphorolytic instead of hydrolytic, and is catalyzed by the enzyme *phosphorylase*, which has been

isolated in crystalline form<sup>14</sup> and studied extensively in Cori's laboratory. This reaction may be visualized as shown on p. 272.

This reaction has a number of interesting features. It is an equilibrium reaction which leads to synthesis of glycogen if there is sufficient glucose phosphate relative to phosphate, whereas breakdown occurs in the opposite case. The synthetic reaction requires a small amount of glucose polymer as a primer. In this phosphorylase reaction, an unbranched chain polymer is formed, with all glucose molecules linked by 1,4 linkages; this product is a linear starch, which stains blue with iodine. The synthesis of branched polymers with both 1,4 and 1,6 linkages (of which glycogen is an extreme example) requires the additional participation of a branching

factor. This enzyme causes the transfer of parts of straight chains to non-terminal positions. Phosphorylase cannot break 1,6 linkages; these are hydrolyzed by a special enzyme.

*Phosphorylase* is known in two forms, *a* and *b*. The first of these is active as such; but phosphorylase *b* requires the addition of adenylic acid, which seemingly acts as a loosely combined coenzyme. It is probable that phosphorylase *a*, too, contains a nucleotide as its active group, but this is bound strongly, and is not identical with adenylic acid. Various tissues contain an enzyme that converts phosphorylase *a* into *b*; this conversion is observed in muscles after exhaustive activity.

Glucose-1-phosphate is transformed into glucose-6-phosphate by the enzyme *phosphoglucomutase*, crystallized by Najjar; glucose-1,6-diphos-

<sup>14</sup> Green, Cori, and Cori: *J. Biol. Chem.*, **142**, 447 (1942).

phate acts as coenzyme for this reaction. The blood glucose is also a source of glucose-6-phosphate in muscle. The transformation cannot be effected by direct combination of glucose with phosphate, since the equilibrium does not favor synthesis. Instead, glucose is phosphorylated by ATP under the influence of the enzyme *hexokinase*:

**Formation of Triosephosphate.** Glucose-6-phosphate, whether formed from glycogen or glucose, is transformed into fructose-6-phosphate in the presence of the enzyme *oxoisomerase*, and the reaction product is phosphorylated once more by ATP to form fructose-1,6-diphosphate. These steps are shown on p. 273.

Fructose-1,6-diphosphate is then split under the influence of the enzyme *aldolase* into two isomeric triosephosphates, dihydroxyacetonephosphate and 3-phosphoglyceraldehyde:

These triosephosphates are interconvertible through the action of another isomerizing enzyme. It is the 3-phosphoglyceraldehyde which undergoes further reaction.

**Oxidative Step.** Triosephosphate is oxidized by pyridine nucleotide (DPN, coenzyme I) and the enzyme *phosphoglyceraldehyde dehydrogenase*, in a reaction which would be expected to yield 3-phosphoglyceric acid. Instead, it is found that 1,3-diphosphoglycerate is formed, while inorganic phosphate (without which the reaction cannot proceed) is taken up (Warburg). One may consider that the dehydrogenation of aldehyde, normally involving a preliminary hydration, in the present case utilizes phosphoric acid instead of water to that effect. The actual reaction mechanism is a problem of considerable interest.<sup>15</sup>

<sup>15</sup> It is the triosephosphate dehydrogenase which seems to be the point of action of iodoacetate poisoning. Under the influence of this drug, glycolysis can be inhibited without immediate effect upon the contractile activity of the tissue (Lundsgaard).

**Formation of Pyruvate.** Diphosphoglyceric acid is transformed into 3-phosphoglyceric acid, ADP acting as the phosphate acceptor. The product is converted into 2-phosphoglycerate and then, by the enzyme *enolase*, into enol-phosphopyruvic acid. This finally donates its phosphate radical to ADP, yielding pyruvate.

**Formation of Lactate.** In the formation of diphosphoglycerate from triosephosphate, a molecule of coenzyme I had been reduced. This is now reoxidized by pyruvate, reducing the latter to lactic acid, which is the end product of glycolysis.

## RESPIRATION

Under aerobic conditions, essentially the same set of reactions takes place as in glycolysis, up to the stage of pyruvate formation. However, the reoxidation of coenzyme I reduced in the triosephosphate dehydrogenation is undertaken by oxidative enzymes and eventually by oxygen. Pyruvate then is not reduced to lactate. Instead, it is completely oxidized in the citric acid cycle (see Chapter 33).

The respiratory enzymes, like cytochromes and cytochrome oxidase (see Chapter 12) are present in different muscles in varying amounts, although muscular activity eventually depends upon respiratory metabolism. There are types of muscle, like the myocardium,<sup>16</sup> which are continuously active and must therefore steadily respire at a sufficiently high rate to meet the energy demands. Such muscles must contain sufficient respiratory enzymes to permit this high rate of metabolism. Other types of muscle, whose activity alternates with periods of rest, frequently are less well endowed with oxidative systems. When such muscles become

<sup>16</sup> Much of the classical work on cytochromes, cytochrome oxidase, yellow enzymes and other oxidation factors was done on preparations of mammalian and pigeon heart muscle.

active, glycolysis takes place in addition to respiration, in an effort to fulfill the energy requirements.

### ENERGY-RICH PHOSPHATES

Neither oxygen nor lactic acid is directly involved in contractility, since muscles can contract anaerobically when glycolysis is inhibited with iodoacetate. Furthermore, increased oxygen consumption and lactic acid production occur only after contraction (Embden). Phosphocreatine and ATP are found to be more closely related to the contractile mechanism. These compounds are examples of the so-called high-energy phosphates,<sup>17</sup> compounds which liberate energy when dephosphorylated, as manifested by the large amount of heat produced in their hydrolysis (about 12,000 calories per mole hydrolyzed). This applies to phosphocreatine and to each of the two pyrophosphate linkages in ATP, but not to the ribose-phosphate linkage. The free-energy effect of the splitting is likewise high, so that such compounds can act as phosphate-group donors for the synthesis of other substances, and can, presumably, also serve to yield energy to be transformed into mechanical work.

**Generation and Utilization of ATP.** The description of the reaction sequence of glycolysis has given examples of how, in the formation of glucose-6-phosphate from glucose and of fructose-1,6-diphosphate from fructose-6-phosphate, ATP acts as a phosphate group donor, and how in other instances, reaction products like diphosphoglycerate or phosphopyruvate transfer phosphate groups to ADP. It is, indeed, the purpose of metabolism to subject the metabolites to such transformations that the phosphate groups contained in them acquire a high group potential, so that they can be transferred to ADP (or AMP, although this, in general, seems to be less important). By such reactions, ATP is regenerated whenever it has been split in other reactions. In glycolysis, 4 moles of ATP are thus formed per mole of hexose decomposed, 2 moles having initially been expended to phosphorylate glucose to the hexose diphosphate stage (only 1 mole in the case of glycogen breakdown; but the formation of glycogen from blood sugar also expends 1 mole of ATP). In respiratory metabolism, there are many other reactions in which ATP is produced, not all of which are known in detail. Aerobic phosphorylation may lead to about 6 moles of ATP generated per mole of O<sub>2</sub> consumed.

**Enzymes and ATP.** A number of enzymes are known which are of interest in connection with the transformations of ATP. The following enumeration is not complete, but is restricted to some enzymes occurring in muscle. Hydrolysis of ATP is effected by *adenosinetriphosphatases*, or ATPases, which split the terminal pyrophosphate linkage, yielding inorganic phosphate and ADP. At least two such enzymes occur in muscle: one of these is myosin itself (Engelhardt and Ljubimova); the other is a particulate entity similar to the microsomal or mitochondrial fractions isolated from other organs (Kielley and Meyerhof). Both enzymes display a complicated dependence on the ion composition of the medium. The particulate ATPase is activated by magnesium and inhibited by cal-

<sup>17</sup> Lipmann: *Advances in Enzymol.*, 1, 99 (1941).

cium; but for pure myosin the opposite is true. In actomyosin systems the situation is more complicated and has not yet been fully explored. The function of the particulate enzyme is probably not related to contractility. Myosin, on the other hand, is a part of the contractile machinery; hence its ATPase activity is a matter of obvious interest. However, it has been stated that the activity of myosin is not sufficient to account for the actual rate of breakdown occurring in sustained tetanic activity. It is probable that the ATPase activity of myosin is but a reflection of a more fundamental reaction which has not yet been recognized, and which may be related to the occurrence of myosin in an organized state in conjunction with other active materials.

Phosphocreatine, on the other hand, is not directly hydrolyzed by muscle enzymes. It can transfer its phosphate group to ADP (and also to adenylic acid, AMP) in the Lohmann reaction:

so that dephosphorylation of phosphocreatine can be effected by a system containing creatine-ATP-phosphophorase, ATPase, and adenine nucleotide. It is held that in living muscle, phosphocreatine acts as a reservoir of  $\sim\text{ph}$ , from which ATP can be restored on short notice. A more fundamental role of phosphocreatine is, however, not at all excluded, and it may be specifically involved in relaxation (Dubuisson).

ATPase removes only one phosphate from ATP, but an enzyme exists (*myokinase*) which catalyzes the transmutation:  $2 \text{ADP} \rightleftharpoons \text{ATP} + \text{AMP}$ . In combination with ATPase, this enzyme can thus effect the complete dephosphorylation of ATP to AMP, which, as mentioned previously, can then be deaminated to inosinic acid (IMP). The latter is formed after prolonged muscular activity, but it is doubtful whether such far-going breakdown occurs normally under optimal conditions. Formation of IMP may be the normal pathway of autolytic nucleotide catabolism in skeletal muscle, but not in heart or other tissues, where adenylic acid is dephosphorylated rather than deaminated (Kerr).

Other enzymes effect the transfer of phosphate from ATP onto other substrates; thus, *hexokinase* catalyzes the reaction:  $\text{ATP} + \text{glucose} \rightarrow \text{ADP} + \text{glucose-6-phosphate}$ . The possible connection of such enzymes, instead of ATPases, with activity metabolism has not yet received sufficient consideration.

**True and Apparent ATPase Activity.** When an isolated enzyme, myosin or some other, splits ATP into ADP and phosphoric acid, without demonstrable participation of other substances, it is no doubt correct to call such an enzyme "adenosinetriphosphatase." It is an interesting question whether this involves phosphorylation and dephosphorylation of the enzyme protein as intermediate steps, but this would not affect the terminology. It is also possible that in more complex systems a set of reactions would occur as follows:

In such a case, X would be a coenzyme of the ATPase.

It should be understood, however, that if a splitting of ATP is observed in a crude tissue extract or in an intact organ, this splitting is not necessarily due to an ATPase, with or without coenzyme, but may be linked with other and irreversible metabolic reactions. Thus, the formation of urea in liver from proper ammonia donors through the functioning of the ornithine-citrulline-arginine cycle (see Chapter 33) involves the splitting of ATP. Likewise, formation of glucose-6-phosphate from ATP and glucose, followed by breakdown of the glucose phosphate or its conversion products, would appear as a hydrolysis of ATP. Such additional metabolic components have been referred to as cosubstrates.<sup>18</sup> The breakdown of ATP in complex tissue systems may well be due to such reactions rather than to ATPase.

**ATP Breakdown and Muscular Activity.** It was shown by Lunds-gaard that, when respiration and glycolysis are eliminated, muscular activity is linked with the dephosphorylation of phosphocreatine. As explained, this proceeds presumably via ATP breakdown. The primary breakdown of ATP was demonstrated recently by comparative analyses of relaxed and contracted muscle, both striated and cardiac.<sup>19</sup> It appears that in each case one cycle of activity is linked with the decomposition of maximally  $5 \times 10^{-7}$  moles of ATP per gram of muscle, as predicted on the basis of physiological data. Thus, we regard the dephosphorylation of ATP as the metabolic reaction primarily connected with contraction. The study of heat production in a single twitch (Hill) supports this same sequence: the contraction heat corresponds to splitting of ATP; relaxation (restoring ATP from phosphocreatine) is almost thermoneutral; and the restitution heat depends on the prevalent type of metabolism, whether glycolytic or respiratory. In the more physiological case of tetanic contraction, the various phases overlap.

Although ATP breakdown has been thus correlated with contraction, nothing warrants the assumption that this breakdown is to be ascribed to direct ATPase activity; rather, it may involve complicated cosubstrate reactions or mechanochemical mechanisms.

## MOLECULAR MECHANISMS

In muscular contraction, chemical energy is directly transformed into mechanical work, and this transformation takes place in the muscle fibril. An explanation for this phenomenon could be given if it were known just what the molecular structure of the fibril is, how this structure is modified to result in contraction, and how this modification is connected with the breakdown of ATP. This objective has not been reached, much less the corresponding analysis of relaxation and of neuromuscular activation. A number of interesting advances, however, warrant the hope that

---

<sup>18</sup> Mommaerts: *Muscular Contraction* pp. 94–95 (see Bibliography). An interesting model of an apparent ATPase system would be formed by choline acetylase, coenzyme A, acetate, choline, and acetylcholine esterase. It is not suggested, however, that this system actually operates as the link between excitation and contraction. See this chapter, p. 279, concerning the possibility that actin may be the cosubstrate.

<sup>19</sup> Mommaerts and Rupp: *Nature*, **168**, 957 (1951); Khairallah and Mommaerts: *Circulation Res.*, **1**, 460 (1953).

an explanation of contraction in terms of actomyosin-ATP interaction may eventually be achieved.

It is possible to prepare threads of actomyosin by extrusion of a solution of this protein into a dilute salt solution. Such threads contract when ATP is added, especially in the presence of some magnesium.<sup>20</sup> Oriented and stronger threads can be made by various devices; these thicken during contraction and can lift weights. Finally, one can prepare bundles of actomyosin filaments in their original configuration by extracting all other constituents from muscle strips. Such fiber preparations become thicker when shortening and develop about the same tension as the original muscle would.<sup>21</sup>

Imperfect though the extruded actomyosin fiber is, it permits the study of the individual protein components. Thus, it has been found that neither myosin nor actin alone can form contractile fibers, but that only the combination of myosin with F-actin is capable of contraction. Apart from the cation requirements, it can be said, then, that contractility is the result of the effect of ATP upon an oriented structure of actin and myosin. The mechanism of this interaction is unknown, but the formulation of the problem in these biochemical terms is itself a great advance.

In addition to its role in combination with myosin, actin itself displays some interesting properties. The polymerization of actin from the G to the F state is linked with the breakdown of ATP in a stoichiometric reaction:

The amount of actin in one gram of muscle is such that, if it should all polymerize at one time,  $5 \times 10^{-7}$  moles of ATP would be split, which is exactly equal to the amount of ATP broken down in one maximal contraction.<sup>22</sup> This equality makes it likely that polymerization takes place early in the activation phase of the contraction, to be followed by contraction of the F-actomyosin formed.

The participation of actomyosin and its components in contraction is further illustrated by the observation that these proteins can be extracted only from relaxed muscle. Contracted muscle yields no actomyosin or myosin; instead there appears a new protein, contractin, albeit in smaller amount (Dubuisson).

## EXPERIMENTS ON MUSCULAR TISSUE

### SEPARATION OF EXTRACTIVES FROM MUSCLE

**1. Creatine.** Dissolve about 10 g. of a commercial extract of meat<sup>23</sup> in 200 ml. of warm water. (Test for protein by biuret and coagulation tests, pp. 171, 188.) Precipitate the inorganic constituents by neutral lead acetate, being careful not to add an excess of the reagent (30 ml. of a 20 per cent solution is about the right amount). Write the equations for the reactions taking place

<sup>20</sup> Szent-Györgyi: *Stud. Inst. Med. Chem. Szeged*, 1, 17 (1942).

<sup>21</sup> Szent-Györgyi: *Biol. Bull.*, 96, 140 (1949).

<sup>22</sup> Mommaerts: *J. Biol. Chem.*, 198, 469 (1952).

<sup>23</sup> Commercial meat extracts vary considerably in their creatine content, and may have to be "fortified" for class use.

here. Allow the precipitate to settle, then filter, and remove the excess of lead in the warm filtrate by hydrogen sulfide. Filter while the solution is yet warm, evaporate the clear filtrate to a syrup, and allow it to stand at least 48 hours in a cool place. Crystals of creatine should form at this point. Examine under the microscope (see Fig. 73). Treat the syrup with 25 ml. of 95 per cent ethyl alcohol, stir well with a glass rod to bring all soluble material into solution, and then filter. When the fluid has drained completely, use a further 10-ml. portion of 95 per cent alcohol to aid in transferring the residue in the beaker to the filter paper, and to wash the material on the filter paper. The purine bases have been dissolved and are in the filtrate, whereas the creatine crystals were insoluble in the alcohol and remain on the filter paper. Remove the crystals and bring them into solution in about 10 ml. of hot water. A little animal charcoal may be added to decolorize the solution. Filter and concentrate the filtrate to small volume. Allow the solution to cool and note the separation of colorless crystals of creatine.<sup>24</sup>

Make the following tests on the crystals:

a. MICROSCOPICAL EXAMINATION. Examine some crystals under the microscope and compare the form with those reproduced in Fig. 73.

b. TRANSFORMATION OF CREATINE INTO CREATININE. Dissolve a portion of the crystals in about 10 ml. of water. Divide into two equal portions. To one portion add 5 ml. of 2 N hydrochloric acid. Evaporate this acidified portion carefully over the free flame and finally to dryness on the water bath. The creatine has been changed into creatinine. Take up the residue in about 5 ml. of hot water, cool, and apply the tests for creatinine as given in Chapter 28 to this extract as well as to the original solution. What are your conclusions?

DIACETYL REACTION. To 5 ml. of a dilute creatine solution add an equal volume of saturated sodium carbonate solution and a few drops of a solution of diacetyl. A pink color should develop. This test has been made the basis of a method for the quantitative determination of creatine (see p. 287).

2. *Preparation of Glycogen.*<sup>25</sup> Grind a few fresh oysters in a mortar with sand.<sup>26</sup> Transfer to an evaporating dish, add water, and boil for 20 minutes. At this point the volume of solution should have been reduced by about one-half. Note the opalescence of the solution. At the boiling point, faintly acidify with acetic acid. Why is this acid added? Filter, and divide the filtrate into two parts.

Test one part of the filtrate as follows:

a. IODINE TEST. To 5 ml. of the solution in a test tube add 5 to 10 drops or more of Lugol's iodine solution, at the same time adding a similar amount of iodine to 5 ml. of water in another tube, this serving as a control. What do you observe? Is this similar to the iodine test upon any other compound with which we have had to deal?

b. REDUCTION TESTS. Does the solution reduce Benedict's solution?

c. HYDROLYSIS OF GLYCOGEN. Add 10 drops of concentrated hydrochloric acid to 10 ml. of the solution and boil for 10 minutes. Cool the solution, neutralize with solid sodium carbonate, and test with Benedict's solution. Does it still

---

<sup>24</sup> For the preparation of pure creatine from creatinine, see p. 801.

<sup>25</sup> For a quantitative experiment showing the effect of diet on the glycogen content of liver, see Chapter 33, p. 1071.

<sup>26</sup> Glycogen may be readily obtained from the livers of well-fed rabbits which have been killed by the intraperitoneal injection of 5 ml. of 25 per cent anhydrous  $\text{MgSO}_4$  per kg. The excised liver is quickly cut into small pieces and dropped into about 150 ml. of boiling water. Continue then as described above.

fail to reduce Benedict's solution? If you find a reduction how can you prove the identity of the reducing substance?

d. **INFLUENCE OF SALIVA.** Place 5 ml. of the solution in a test tube, add 5 drops of saliva, and place in the water bath at 40° C. for 10 minutes. Does this now reduce Benedict's solution?

To the second part of the glycogen filtrate add 3 to 4 volumes of 95 per cent alcohol. Allow the glycogen precipitate to settle, decant the supernatant fluid, and filter the remainder. Transfer the glycogen to a watchglass and heat on a water bath to remove the alcohol; then subject it to the following tests:

a. **SOLUBILITY.** Try its solubility in cold and hot water, in alcohol, and ether.

b. **IODINE TEST.** Place a small amount of the glycogen in a depression of a test tablet and add 2 to 3 drops of dilute iodine solution. The same wine-red color is observed as in the iodine test upon the glycogen solution.

## NUCLEOTIDES OF MUSCLE

1. *Preparation of Adenosinetriphosphate from Muscle.* Into the peritoneal cavity of a rabbit inject a solution containing 25 per cent anhydrous magnesium sulfate in the proportion of 5 ml. per kilogram of body weight. When the animal is unconscious, slit its throat and bleed it as thoroughly as possible, then remove the skin, and pack the carcass in ice for an hour or so to chill thoroughly. Excise the muscle tissue of the legs and back, and grind in a chilled meat-grinder. (All of the remaining steps should be carried out in a cold room or with thorough chilling of reagents, containers, etc., by ice.) Mix the minced muscle with an equal weight of ice-cold 10 per cent trichloroacetic acid, and after thorough mixing, filter by suction. Extract the residue with an equal weight of 4 per cent trichloroacetic acid and filter as above. Neutralize the combined filtrates to pH 6.8 with 40 per cent sodium hydroxide solution. Add 50 per cent barium acetate solution to complete precipitation, and allow the precipitate to settle. Decant the supernatant, centrifuge down the precipitate, and wash it once with water.

Treat the precipitate with 0.2 N nitric acid, with stirring, to a pH of 3, or to the first blue with Congo red paper. Centrifuge and pour off the supernatant, rejecting the insoluble material. Add to the supernatant 3 to 5 ml. of Lohmann's reagent<sup>27</sup> for every kilogram of muscle used. Allow to stand at 0° for 15 minutes and centrifuge. Suspend the precipitate in water made faintly acid with nitric acid, treat for 1 hour with hydrogen sulfide to decompose the mercury salt, and filter. Aerate the filtrate to remove excess hydrogen sulfide, then neutralize the filtrate to pH 6.8 with dilute sodium hydroxide solution. Add 25 per cent barium acetate solution to complete precipitation, avoiding an excess. Filter off the precipitate by suction and wash it successively with 1 per cent barium acetate solution, 50 per cent alcohol, 75 per cent alcohol, 95 per cent alcohol, and ether. Dry the product in air and store well-stoppered in the cold. The yield is roughly 3 g. of the barium salt per kilogram of muscle used.

This product usually contains some inorganic phosphate; it may be further purified, with a lower yield, by redissolving in cold 0.1 N hydrochloric acid, neutralizing to pH 6.8 as above, and filtering off the precipitated barium ATP, which is then washed with alcohol and ether and dried as above. The pure

<sup>27</sup> To prepare Lohmann's reagent, add 25 ml. of concentrated nitric acid to 100 g. of mercuric nitrate octahydrate, followed by 25 ml. of water. Warm to dissolve.

salt has the empirical formula  $C_{10}H_{12}O_{13}N_5P_3Ba_2 + xH_2O$ , the water content depending upon the extent of drying. Purity is usually established by the following criteria: (1) The molecular ratio of nitrogen to phosphorus, as established by total N and total P analyses, should be 5:3; (2) the inorganic phosphate content should be very low; (3) the "labile phosphate" (see below) should be two-thirds of the total phosphate after correcting the latter for any inorganic phosphate present.

2. *Conversion of Barium ATP to Sodium ATP.* Dissolve 200 mg. of the barium salt in 6 ml. of ice-cold 0.1 N hydrochloric acid in a centrifuge tube. Add 60 mg. of anhydrous sodium sulfate dissolved in a little water, stir, and centrifuge. Decant the supernatant and wash the precipitated barium sulfate several times with small portions of cold water containing a trace of hydrochloric acid. Neutralize the combined supernatant and washings to pH 7.5–8.5 as desired, analyze an aliquot for inorganic and labile phosphate, and on the basis of this analysis dilute to the desired concentration of sodium ATP. This solution is relatively stable for some weeks in the cold, but undergoes slow hydrolysis, the extent of which should be established before use.

3. *Conversion of Ba-ATP into Soluble Salts by Means of a Cation-exchange Resin.* Dissolve 200 mg. of the barium salt in 6 ml. cold 0.1 N hydrochloric acid, and dilute to about one-half of the volume eventually desired. Prepare a column of 3 cm. height, in a tube of about 1 cm. width (closed near the bottom with a plug of glass wool or a fritted glass disc), of a cation-exchange resin in the potassium or sodium cycle.<sup>28</sup> Filter the solution through the column at a rate of a few ml. per minute, and wash the column with water. The emerging solution is devoid of barium but is usually still slightly acid. It is adjusted to the desired pH with KOH or NaOH and brought to the required volume.

This procedure is more convenient than the precipitation of barium as sulfate, and is also effective in removing traces of heavy metals which would interfere in many enzyme experiments.<sup>29</sup>

4. *Analysis of Adenosinetriphosphate.* Prepare a solution of adenosinetriphosphate in cold 0.1 N hydrochloric acid, containing approximately 1 mg. of the salt per ml. Analyze aliquots of this solution as follows: (1) **INORGANIC PHOSPHATE.**<sup>30</sup> Dilute 1 ml. to 4 ml. with water, add 1 ml. of 5 N sulfuric acid, followed by 1 ml. of 2.5 per cent ammonium molybdate and 0.4 ml. of the Fiske-SubbaRow aminonaphtholsulfonic acid reagent (see Chapter 23). Dilute to 10 ml. with water, mix, allow to stand 10 minutes, and read in a photometer at 660  $m\mu$  wavelength. Compare with a standard containing 0.05 mg. P, treated in the same way. (2) **"LABILE PHOSPHATE."** Dilute 0.5 ml. of solution to 4 ml. with water, add 1 ml. of 5 N sulfuric acid, place in boiling water for 30 minutes.<sup>31</sup> Cool, make up to 5 ml. again, and continue with the addition of ammonium molybdate, etc., as described above. The phosphate

<sup>28</sup> Made by cleaning Amberlite IR 100 or 120, or Dowex 50, by alternate washing in acid and base, finally bringing the resin to the required state with about 0.5 M  $Na_2CO_3$  or  $K_2CO_3$ , followed by rinsing with water.

<sup>29</sup> Good preparations of K- or Na-ATP are now available commercially at moderate prices.

<sup>30</sup> In this and subsequent analyses, if barium is present, a precipitate of barium sulfate will form during the procedure. This is centrifuged down after color development and before reading.

<sup>31</sup> According to Lohmann, the "labile phosphate" of ATP is liberated by 7 minutes' hydrolysis in N hydrochloric acid at 100° C. Fiske and others claim that 15 minutes are required. When N sulfuric acid is used, a 30-minute period has been found necessary.

content, corrected for the inorganic phosphate already present, represents the "labile phosphate" of ATP. It should be two-thirds of the total ATP phosphorus.<sup>32</sup> (3) TOTAL PHOSPHORUS. Transfer a 1 ml. portion of the ATP solution to a large test tube or micro-Kjeldahl flask and add 2.5 ml. of 5 N sulfuric acid. Heat over a microburner until the water has boiled off and the residual fluid is brown or black. Add 1 drop of 30 per cent hydrogen peroxide and boil until clear. Cool, transfer to a 25-ml. graduated flask, with washings to about 18 ml. volume. Add 2.5 ml. of ammonium molybdate and 1 ml. of aminonaphtholsulfonic acid reagent. Dilute to 25 ml., mix, and allow to stand 10 minutes. Compare in a photometer against a standard containing 0.1 mg. P digested with acid, etc., just as was the unknown. A blank of water alone should also be run through the entire procedure, to correct for any phosphorus in the reagents. The total P of the sample, corrected for any inorganic P present, represents ATP phosphorus. (4) TOTAL NITROGEN. Determine by any suitable micro-Kjeldahl method (see Chapters 23 and 31). A 4-ml. portion of the ATP solution described above will contain about 0.3 mg. of nitrogen. The N:P ratio on a molecular basis should be 5:3. (5) ULTRA-VIOLET ABSORPTION. Measure the absorption spectrum of a suitably diluted neutral or acid solution of ATP (containing about 10 to 40 mg. per liter) between 230 and 300 m $\mu$ . The absorption maximum should be situated at 258 to 260 m $\mu$ . The adenine content can be calculated on the basis of an extinction coefficient of 1.6 at the maximum for a  $10^{-4}$  molar solution. The adenine:N:P ratio should be 1:5:3, on a molecular or atomic basis.

5. *Preparation of Adenylic Acid from Adenosinetriphosphate (Kerr)*. Dissolve 2.5 millimoles of barium adenosinetriphosphate (93 mg. of ATP phosphorus equals one millimole) in a flask containing about 100 ml. of 0.1 N hydrochloric acid, and add a few drops of phenolphthalein followed by sufficient barium hydroxide solution to produce a permanent pink color. Attach a reflux condenser to the flask and heat to boiling over a free flame. Boil for 30 minutes, maintaining the reaction just alkaline to phenolphthalein by the continuous addition of barium hydroxide solution in small portions through the condenser tube. Cool to room temperature, add sufficient N hydrochloric acid to the flask contents to dissolve the precipitate, and dilute to about 1,750 ml. with water. Again neutralize to phenolphthalein with barium hydroxide, and allow the precipitate to settle. Remove the supernatant by decantation and filtration, discarding the precipitate. To the supernatant add sufficient acetic acid to make the final acid concentration 0.2 per cent, followed by 50 ml. of 20 per cent mercuric acetate solution per liter of fluid present. Allow the precipitate to settle overnight, separate it by decantation and centrifugation, and wash it once with 0.5 per cent mercuric acetate solution. Suspend the washed precipitate in about 50 ml. of water containing a few drops of 2 N sulfuric acid and treat with hydrogen sulfide for one hour. Filter off the precipitated mercuric sulfide and pass air through the filtrate to remove excess hydrogen sulfide. The volume at this point should not be over 25 ml. per millimole of starting material. Add acetone to the solution at 20° C. to the first permanent turbidity (not over 1.5 volumes). Allow to stand on ice overnight, filter and discard the precipitate. Bring the filtrate to room temperature and again add acetone to the point of turbidity. Again chill overnight. Separate the crystalline adenylic acid by centrifugation. Repeat the addition of acetone as described until a total of 3 volumes has been

<sup>32</sup> Determination of the acid-labile P (2 moles per mole ATP) is a method frequently used for the determination of ATP. It is a popular misconception that this can also be used to prepare adenylic acid. In reality, the nucleotide is split by this procedure into adenine, ribose-5-phosphate, and inorganic phosphate.

added. Drive off excess acetone from the separated adenylic acid by gentle warming. Recrystallize by dissolving in the minimal amount of hot water, filtering quickly, and allowing the filtrate to stand in the cold overnight. Centrifuge or filter off the crystals and repeat the recrystallization procedure five or six more times to obtain a final product which has the theoretical N:P ratio of 5:1 and the correct melting point of  $189^{\circ}\text{C}$ . The final crystals are washed with a little alcohol and ether and dried. The mother liquors from the various recrystallizations may be saved, combined, and treated with 3 volumes of acetone, followed by recrystallization as above, to obtain more adenylic acid which is less pure.

## PREPARATION AND REACTIONS OF MYOSIN AND ACTIN

1. *Preparation of a Crude Myosin Solution.* Anesthetize and kill a lean rabbit, as described for the preparation of ATP, and chill and excise the musculature in the same manner. Mince the tissue in a chilled meat-grinder, and extract immediately for 20 minutes in the cold with 3 volumes of 0.6 M KCl, 0.05 M  $\text{NaHCO}_3$ . Collect the extract by centrifugation or straining through several layers of gauze, and dilute with 10 to 12 volumes of cold water (redistilled in a glass still, or purified through a mixed-bed ion-exchange resin, in a so-called water-demineralizer which should be made of plastic without metal). Allow the precipitated myosin to settle in the cold, siphon off most of the supernatant solution, and collect the myosin by centrifugation. Redissolve the myosin by the addition of a measured amount of 2 M KCl solution, and add water until the final KCl concentration is 0.5 M.

2. *Formation of Actomyosin.* Proceed with the extraction of minced muscle as in the previous experiment, but incubate the tissue with the alkaline KCl solution for various lengths of time, up to 18 to 24 hours in the cold, with occasional stirring. Take 50 ml. aliquots at regular intervals, and obtain the extracts from these by centrifugation followed by filtration through glass wool. Formation of actomyosin is indicated by a strong rise in viscosity and flow birefringence (see below). Actomyosin can be prepared from the extract by precipitation and resolution, as described for myosin.

3. *Observation of Flow Birefringence.* A simple apparatus can be assembled with the aid of two 2-inch polaroid discs mounted vertically above each other about 4 to 6 inches apart and illuminated from below. The polaroids are crossed, so that no light is transmitted. A 30-ml. glass beaker is selected such that, when examined in the polariscope thus assembled, its bottom does not show significant birefringence. A crude or purified solution of actomyosin is placed in the beaker to about 1 cm. depth, and this solution, while being observed between the crossed polaroids, is gently rotated by swirling the beaker by hand. The rotating solution shows a dark cross (the isoclyne cross) on an illuminated background. This phenomenon is due to the orientation of very long particles (molecules or swarms) in the streaming gradient, which leads to a regular alignment giving rise to birefringence, except for those orientations that are parallel with the vibrational axes of the polarizer and analyser.

4. *Preparation of Crystalline Myosin.*<sup>33</sup> Prepare minced rabbit muscle as previously described, and extract 300 g. in the cold with 1 liter of 0.3 M KCl,

<sup>33</sup> This procedure combines different features of the methods of Szent-Györgyi, of Weber, and of Mommaerts and Parrish.

0.15 M K-phosphates (pH 6.5) for 15 minutes with gentle stirring. Add 4 liters of cold water, and strain through several layers of gauze. Dilute with water to 12 liters final volume, and leave in the cold for 3 hours. Siphon off the supernatant solution as far as possible, collect the protein by centrifugation, dissolve it by the addition of 60 ml. of 2 M KCl and 30 ml. of a solution 0.25 M with respect to  $K_2HPO_4$  and  $KH_2PO_4$  each, and add water to a final volume of 300 ml. (pH 6.5 to 6.8, ionic strength 0.5). Clarify this solution by centrifugation and filtration through glass wool or Filter-cel. Add 240 ml. of water, and remove the precipitated actomyosin by strong centrifugation. (The solution may remain somewhat turbid through micellar aggregation of myosin at this ionic composition.) Place the solution in a large, cooled container and slowly (10 minutes) add 4 liters of cold water with continuous stirring. The myosin will precipitate in the form of fine, microscopically visible needles which give a silky sheen to the suspension. The steps for the removal of actomyosin and the crystallization may be repeated, and the myosin finally dissolved in 0.5 M KCl, and dialyzed against this solvent.

Pure myosin shows no flow birefringence with the simple method described in Experiment 3 of this section.

5. *Demonstration of Adenosinetriphosphatase Activity of Myosin Preparations.* Place 2 ml. of myosin solution (diluted in 0.5 M potassium chloride so as to contain 1 to 2 mg. of protein) in each of two test tubes. Add 1 ml. of 4 per cent sodium bicarbonate solution and 0.5 ml. of 0.1 per cent anhydrous calcium chloride solution. To Tube 1, which is a control, add 0.5 ml. of 20 per cent trichloroacetic acid solution. To each tube add 0.5 ml. of sodium ATP solution containing a known amount (0.1 to 0.2 mg.) of "labile phosphorus." Dilute the contents of the control tube immediately to 10 ml. with water, mix, and filter. Allow the second tube to stand at room temperature for 30 minutes, then add 0.5 ml. of 20 per cent trichloroacetic acid solution, dilute to 10 ml., mix, and filter. Determine the inorganic phosphate content of each filtrate as described above, using a 2 ml. aliquot. Correct for the value of the control by subtraction. What fraction of the labile phosphate of the ATP has been converted into inorganic phosphate by the myosin? If desired, this experiment may be repeated at varying time intervals to establish the rate of enzyme action.

6. *Preparation of Muscle Fibrils (Perry).* Rabbit muscle is dissected, chilled, and minced as for the preparation of myosin. The mince is homogenized in a Waring blender for 2 minutes with 8 volumes of 0.08 M borate buffer, pH 7.1, at 0° C. The following operations are likewise carried out at this temperature. The homogenate is centrifuged 15 minutes at about 600 g., and the sediment is resuspended in the original volume of borate. This is homogenized once more for 2 minutes. This suspension is centrifuged for 20 minutes at 600 g.; the supernatant solution is discarded, while the lighter-colored upper layer of the sediment is taken up in fresh borate buffer. This suspension is then freed from coarser material by centrifugation for 5 minutes at 300 g. The suspension is then subjected to several cycles of centrifugation (20–30 minutes at 600 g.) and resuspension. Toward the end of the preparation 0.1 M KCl may be used instead of borate buffer.

Such suspensions form turbid viscous fluids which show a strong flow birefringence. Microscopic observation reveals the presence of thin threads, in many of which the cross-striation is clearly visible. The addition of ATP results in rapid contraction, revealed by loss of birefringence and precipitation of flocculent material. Fibril preparations are very active as adenosine-

triphosphatase, but contain also myokinase and adenylate deaminase activity; the myokinase can be removed by washing ATP-contracted fibrils with water or dilute KCl solution.

**7. Contractile Fiber Preparation (Szent-Györgyi).** A rabbit is killed as for the preparation of myosin, and eviscerated. The body is placed in a refrigerator for 15 minutes and is finally cooled in ice. The psoas muscle is exposed by removing the sides and the anterior part of the body, and is liberated by placing the index finger under it and moving the finger in a longitudinal direction. Then the muscle is lifted slightly and punched through with a probe or with small forceps with closed tips so as to separate a fiber bundle about 2 mm. in diameter from the bulk of the muscle. This fiber bundle is then separated over the whole length by moving the forceps parallel to the fibers. A small stick (applicator rod) is placed alongside, and the fiber bundle is tied to it at both ends; whereupon, it is cut free. Other fiber bundles are isolated in the same fashion. Each bundle with its rod is placed in 50 per cent glycerol at 0° C. (maintained with melting ice in a thermos bottle, placed in a refrigerator). The fluid is exchanged twice for fresh, precooled 50 per cent glycerol, at daily intervals, after which the fibers can be stored at -20° C. for months. Before use, the fibers are placed in 15 per cent glycerol at 0° C. for one hour, and are then split longitudinally into finer threads by pulling with fine forceps.

Contraction can be observed by placing such fibers in fresh muscle extract (made by suspending freshly minced muscle in an equal volume of boiling water and filtering through cloth), or in 0.2 per cent neutralized ATP in 0.1 M KCl, 0.001 M MgCl<sub>2</sub>.

**8. Preparation of Actin (Straub, with modifications of Bailey and Tsao).** Muscle is extracted for 10 minutes, and the mince is diluted threefold with water, as in the preparation of crystalline myosin. After straining through gauze, the residue is washed by gentle stirring in 4 volumes of 0.05 M NaHCO<sub>3</sub> (the pH becomes about 7) and then in 10 volumes of water; each washing lasts 20-30 minutes. The residue is pressed as dry as possible in a cloth, and is then extracted twice in a Waring blender for 1 minute with 2 volumes of cold *n*-butanol (let it stand for 30 minutes), and finally 3 times with 2 volumes of acetone, after which it is dried in the air.

The dry fiber is extracted with 25 volumes of water or (in order to assure a good yield) ATP solution (about 60 mg per liter, pH 8.2). The material does not wet easily, and must be thoroughly stirred for 30 minutes in the cold. The solution is filtered by suction and centrifuged.

This extract contains actin in the globular form (usually about 5 mg. per ml., of about 50 per cent purity), so that its viscosity is low, and no birefringence is shown. After the addition of KCl to a final concentration of 0.1 M, rapid formation of fibrous actin takes place. This is evident from an increase in viscosity, frequently leading to a gelation of the solution, and by the appearance of a most intense flow birefringence.

## SOME CHEMICAL DETERMINATIONS ON MUSCLE

In this section a few selected analyses on muscular tissues are given without specification as to the origin of the tissue or its physiological state. These experiments can be performed on frog muscles, rat diaphragms, or other suitable materials.

1. *Extraction Procedure.* About one g. muscle is extracted in the cold with 3 ml. of 0.5 N perchloric acid, and the residue (after filtration or centrifugation) is re-extracted with 2 ml. of the same reagent. The combined extracts are rapidly neutralized to a faint pink color with phenolphthalein, and are left in the cold to assure precipitation of the potassium perchlorate (the residual solubility of which is about 0.05 M at 0° C.). The solution is filtered quantitatively into a 10 ml. volumetric flask, the phenolphthalein is removed by extracting twice with ether (withdrawing the ether with an eyedropper), and the solution is brought to volume. Alternatively, neutralization can be controlled with the glass electrode.

2. *Chromatographic Separations of Adenosinepolyphosphates (Cohn and Carter).* A column is prepared (2 cm. height, 1 cm. diameter) of the anion-exchange resin Dowex 1 in the chloride cycle<sup>34</sup> in a suitable chromatography tube. A muscle extract, prepared as described above, is diluted 5 times with water (in order to reduce the salt content, which would counteract retention by the column), the pH is adjusted to 9.5–10, and the solution is passed slowly through the column, which retains the nucleotides quantitatively. Elution is effected by successive application of 100–150-ml. portions of 0.003 N HCl; 0.01 N HCl, 0.02 M NaCl; and 0.01 N HCl, 0.2 M NaCl. These solvents elute AMP and IMP, ADP, and ATP, respectively. The eluates are collected in fractions of about 10 ml., in each of which the nucleotide is determined by measurements of the ultraviolet absorption, as described on p. 283 for ATP or, if no facilities for this are available, by the Bial test, p. 845.

3. *Separation of Adenosinepolyphosphates by Paper Chromatography.* Small amounts of muscle extract (e.g., 0.02 ml.) are applied to strips of suitable filter paper (e.g., Whatman No. 4); the size of each spot is kept small by intermittent application while drying after each delivery in a current of air. The chromatogram is developed by means of a solution of 60 volumes of *n*-propanol, 10 volumes of water, and 30 volumes of concentrated ammonia (Eggleton). Nucleotides can be located by observation in short-wave ultraviolet light by means of a Mineralight lamp. The experimental details of paper chromatography are described on p. 18.

4. *Determination of Free Creatine.* For this and the following determinations, the tissue extraction should be carried out with especial care and rapidity. It is advisable to use 0.5 N perchloric acid which contains 20 per cent ethanol, cooled to –10° C., and to perform all manipulations at the lowest possible temperature until the extract is neutralized. In a 10-ml. volumetric flask, mix 1 ml. extract, a few ml. of water, 2 ml. of alkaline  $\alpha$ -naphthol solution (0.5 g. freshly dissolved in 1 liter of stock alkali: 60 g. NaOH and 160 g. Na<sub>2</sub>CO<sub>3</sub> per liter), and 1 ml. of diacetyl (a freshly prepared 1:20 dilution of a 1 per cent stock solution). Compare the color or absorbancy (at 520 m $\mu$ ) with that given by a standard solution containing 0.005 mg. creatine treated in the same manner.

5. *Determination of Free Inorganic Phosphate and of Phosphocreatine (Ennor and Stocken's adaptation of the method of Berenblum and Chain).*

(a) INORGANIC PHOSPHATE. In a separatory funnel, place 2 ml. of neutralized muscle extract, 1 ml. of 0.25 N H<sub>2</sub>SO<sub>4</sub> containing 4 per cent NaCl, and 1 ml.

<sup>34</sup> The resin is cleaned by alternate washings with acid and alkali, and is finally treated with 3 N HCl and washed with water until neutral.

of 0.5 per cent ammonium molybdate. Add these reagents in rapid sequence (5 seconds in total being permissible) and shake *immediately* for 10 seconds with 8 ml. of isobutanol. After separation of the phases (which is facilitated by the salt added to the sulfuric acid solution), wash twice with 4 ml. of 1 N  $\text{H}_2\text{SO}_4$ , swirling but not shaking the contents of the funnel each time. In parallel experiments, run a blank (2 ml. water) and a standard (2 ml., containing about 10  $\mu\text{g. P}$ ). The isobutanol phases are then shaken for one-half minute with 10–12 ml. of stannous chloride solution (1 ml. of a stock solution of 10 g.  $\text{SnCl}_2$  in 25 ml. of concentrated  $\text{HCl}$ , freshly diluted with 200 ml. 2 N  $\text{H}_2\text{SO}_4$ ). The aqueous layer is removed, and the alcoholic layer is quantitatively transferred to a 10-ml. volumetric flask, the funnel is washed with ethanol, and the solution brought to volume with this solvent. Colorimetric readings are then performed at about 610  $\text{m}\mu$ .

(b) INORGANIC PHOSPHATE + CREATINEPHOSPHATE. Place 1 ml. extract in a separatory funnel with 2 ml. 1 N  $\text{H}_2\text{SO}_4$  and 1 ml. 5 per cent molybdate, and keep this at room temperature for 15 minutes. Run a blank determination with 1 ml. water, and a standard with 1 ml., containing 10  $\mu\text{g. P}$ . After it has stood, extract with isobutanol, wash with  $\text{H}_2\text{SO}_4$ , and reduce with  $\text{SnCl}_2$  as described for inorganic phosphates.

**6. Demonstration of Phosphates and Magnesium in Muscle (Hürthle's Experiment).** Tease a very small piece of frog's muscle on a microscope slide. Expose the slide to ammonia vapor for a few moments, then adjust a cover glass, and examine the muscle fibers under the microscope. Note the large number of crystals of ammonium magnesium phosphate distributed everywhere throughout the muscle fiber, thus demonstrating the abundance of phosphates and magnesium in this type of muscle preparation (see Fig. 226).

**7. "Fuchsin-frog" Experiment.** Inject a saturated aqueous solution of fuchsin S into the lymph spaces of a frog two or three times daily for one or two days, in this way thoroughly saturating the tissues with the dye. Pith the animal (insert a heavy wire or blunt needle through the occipito-atlanto-toid membrane), remove the skin from both hind legs, and expose the sciatic nerve in one of them. Insert a small wire hook through the jaws of the frog and suspend the animal from an ordinary clamp or iron ring. Pass electrodes under the exposed sciatic nerve, and after tying the other leg to prevent any muscular movement, stimulate the exposed nerve by means of make and break shocks from an induction coil. The stimulated leg responds by pronounced muscular contractions, whereas the tied leg remains inactive. Continue the stimulation until the muscles are fatigued. The muscular activity has caused the production of lactic acid and this in turn has reacted with the injected fuchsin to cause a pink or red color to develop. The muscles of the inactive leg still remain unchanged in color.

The color of the fuchsin S when injected is red; this substance acts as a pH indicator, however, and is colorless at the pH of normal tissues. Upon stimulating the muscles, as explained above, lactic acid is formed and the resultant lowering of pH regenerates the original color of the dye.

## Nervous Tissue

In common with the other solid tissues of the body, nervous tissue contains a large amount of water. The percentage of water present depends upon the particular form of nervous tissue, but in all forms it is invariably greater in the gray matter than in the white matter. Embryonic nervous tissues also contain a larger percentage of water than the tissues of the adult. The gray matter of the brain of the fetus, for instance, contains about 92 per cent of water, whereas the gray matter of the brain of the adult contains approximately 83 to 84 per cent. Adult whole brain (mixed gray and white matter) has an average water content of 77 to 78 per cent; human spinal cord contains about 75 per cent of water.

The solids of nervous tissue include proteins, lipides, extractives, and inorganic salts. In adult whole brain the relative amounts of these various components, in percentage of the total solids, are approximately as follows: proteins 38 to 40 per cent, lipides 51 to 54 per cent, and extractives (including inorganic salts) 8 to 9 per cent. Other parts of the nervous system may show a somewhat different distribution.

**The Proteins.** The proteins of nervous tissue which have been fairly well characterized include several globulins, nucleoprotein, and the albuminoid neurokeratin. Two of the globulins coagulate at 47° C. and 70° to 75° C., respectively; the nucleoprotein coagulates at 56° to 60° C. The relatively low coagulating temperature of one of the globulins of nervous tissue may be of importance in connection with the nervous manifestations of heat prostration.

**The Lipides.** Many types of lipides occur in nervous tissue. Those which have been reasonably well characterized include (1) phospholipides or phosphatides, (2) cerebrosides or glycolipides, (3) sulfolipides or sulfatides, (4) gangliosides, and (5) cholesterol. Other types will doubtless be recognized as progress continues in this field. It will be noted that the lipides are chiefly of the compound type; there is little or no true fat in nervous tissue. For example, of the 54 per cent of cerebrum solids which are composed of lipide material, the phosphatides constitute approximately 28 per cent, cholesterol 10 per cent, cerebrosides 7 per cent, and the remaining 9 per cent consists chiefly of sulfatides and other relatively poorly characterized and similar material. It has been shown that the relative amounts of certain of the lipides present in the brain may be influenced by age and sex.

**PHOSPHOLIPIDES (PHOSPHATIDES).** The phospholipides or phosphatides include (1) lecithins, (2) cephalins, and (3) sphingomyelin.

*Lecithins.* The lecithins are sometimes spoken of as "phosphorized fats." Their relationship to the fats is indicated by the formula of a typical lecithin.

This lecithin is called oleyl-stearyl-lecithin. On hydrolysis it yields oleic acid, stearic acid, glycerol, phosphoric acid, and choline. Chemically, this compound may be regarded as an ester of choline and a phosphatidic acid, and is therefore a phosphatidyl choline. The phosphatidic acids themselves contain fatty acids, glycerol, and phosphoric acid (but no choline), and have been isolated from tissues as the calcium salts. There is some question whether phosphatidic acids exist as such in tissues, or are produced from lecithins by enzymatic removal of choline during the treatment of the tissue.

There are different lecithins, depending upon the character of the fatty acid radicals. Most of the naturally occurring lecithins contain at least one unsaturated fatty acid radical, but there are instances where both fatty acid radicals are found saturated. The saturated fatty acids found include palmitic and stearic. The unsaturated acids are oleic, linoleic, linolenic and arachidonic (see Chapter 3). Representative types of the lecithin molecule have been synthesized in the laboratory, and in some instances found to be identical with material isolated from natural sources.

It is clear from the structure given above that two isomeric forms of a lecithin molecule are possible, depending upon whether the phosphoric acid-choline group is attached to the  $\alpha$  (terminal) or  $\beta$  (middle) carbon of the glycerol residue; such lecithins are known as  $\alpha$ - and  $\beta$ -lecithins respectively. There is no satisfactory evidence at present that  $\beta$ -lecithins occur naturally.

The lecithins are not confined to the nervous tissues but are found in nearly all animal and vegetable tissues, where they appear to be primary constituents of the cell. Lecithin is soluble in chloroform, ether, alcohol, benzene, and carbon disulfide. It may be precipitated from chloroform or alcohol-ether solution by acetone. Lecithin may be caused to crystallize in the form of small plates by cooling the alcoholic solution to a low temperature. It has the power of combining with acids, bases, and certain salts, such as cadmium chloride, and the hydrochloric acid salt forms a double salt with platinic chloride.

Pure lecithin is colorless; it readily turns brown on exposure to air, presumably because of oxidation of the unsaturated fatty acids present. The choline-phosphoric acid portion of the lecithin molecule is highly water-soluble; the fatty acid portion is insoluble in water but soluble in fats.

Lecithin forms colloidal solutions in water which are of the hydrophilic or emulsoid type (see Chapter 1). If a portion of solid lecithin is placed in water and then observed under the microscope, the lecithin will be seen to diffuse out into the water in the form of long curving strands ("myelin forms") which bear a remarkable resemblance to the protoplasmic protuberances of lower forms of life. The hydrophilic nature of the lecithin molecule may be of importance in connection with the structure and properties of cell membranes.

*Choline* is one of the products of hydrolysis of lecithin, accounting for about 15 per cent of the molecule. It is trimethyl-hydroxyethyl-ammonium hydroxide, and has the following structure:

Choline is a moderately strong base, and forms a crystalline double salt with platinic chloride. In addition to its presence in the lecithin molecule, choline is found widely distributed elsewhere in nature, either free or combined, and appears to play an important part in a variety of physiological processes. In combination with acetic acid the compound acetylcholine is of significance in nerve activity, as discussed later. In the diet choline has been shown to be a source of the labile methyl group (methyl attached to nitrogen or sulfur), which is an important dietary requirement. Further aspects of the biochemistry of choline will be found in Chapters 33 and 35.

*Cephalins.* The cephalins differ from the lecithins in both solubility and chemical structure. Differences in alcohol solubility are used to separate the lecithin fraction from the cephalin fraction of tissue extracts. Chemically, the cephalin fraction is found to be heterogeneous and to contain at least three types of compounds. Two of these types differ from the lecithins in that the choline of the lecithin molecule is replaced by either ethanolamine (colamine),  $\text{CH}_2\text{OH}\cdot\text{CH}_2\text{NH}_2$ , or serine,  $\text{CH}_2\text{OH}\cdot\text{CHNH}_2\cdot\text{COOH}$ . These two types of cephalins are therefore known as phosphatidyl ethanolamine and phosphatidyl serine respectively. As with the lecithins, the nature and type of fatty acid residues joined to glycerol in the cephalins may vary, and the problems of isomerism are similar to those discussed above for lecithin.

A third type of cephalin, less well defined than the other two types, yields inositol as a characteristic hydrolytic product, along with fatty acids, phosphoric acid, ethanolamine, and possibly galactose and tartaric acid. According to Folch, the inositol-containing phosphatide from brain, called diphosphoinositide, is chemically distinct from the more complex inositol-containing phosphatide isolated from the soybean by Woolley and named lipositol. Further work is required to clarify this situation.

Lysolecithin and lysocephalin are prepared by treating lecithin or cephalin with cobra venom. An enzyme present in the venom splits off

the unsaturated fatty acid radical leaving the structure otherwise unchanged. Compounds of this type have a strong hemolytic action on red cells and the hemolytic action of venom is probably brought about in this way. These lysophosphatides combine readily with cholesterol, molecule for molecule, the resulting compound having no hemolytic power.

*Sphingomyelin.* Sphingomyelin represents a third type of phospholipide found in nervous tissue. It is a diaminomonomophosphatide made up of a molecule each of fatty acid, phosphoric acid, and the bases choline and sphingosine.

**Sphingosine**

Among the fatty acids found have been the saturated acids—lignoceric,  $\text{C}_{24}\text{H}_{48}\text{O}_2$ , and another acid, probably hydroxystearic. The fatty acid is apparently in an amide linkage with the amino group of sphingosine. The complete structure would be as follows, R indicating the fatty acid radical.

**Sphingomyelin**

The content of sphingomyelin (and of lecithin as well) is considerably increased in the liver and spleen in the condition known as Niemann-Pick's disease.

**ACETAL PHOSPHOLIPIDES (PLASMALOGENS).** Phospholipides which under suitable conditions give a positive test for aldehydes were first described by Feulgen and given the name *plasmalogen*. These substances are found to contain fatty acid aldehydes joined in acetal linkage to the glycerol of compounds having the basic lecithin or cephalin structure.

**Acetal phospholipide**

In this structure, R represents the remainder of a fatty acid aldehyde chain, and the nitrogenous base is ethanolamine. The crystalline acetal phospholipide isolated by Thannhauser et al.<sup>1</sup> from beef brain contained

<sup>1</sup> Thannhauser, Boncoddio, and Schmidt: *J. Biol. Chem.* **188**, 417 (1951).

palmitic and stearic aldehydes, glycerol, phosphoric acid, and amino-ethanol. The presence of a serine-containing acetal phospholipide in brain has also been reported. Nothing is known as yet concerning the function or physiological significance of acetal phospholipides.

**CEREBROSIDES.** The cerebrosides (sometimes called glycolipides because of their carbohydrate content) are lipides containing carbohydrate, one fatty acid, and sphingosine, but no phosphoric acid or glycerol. Examples include phrenosine, kerasine, nervone, hydroxynervone. Two general categories are now known: (1) galactolipides, containing galactose as the component sugar, and (2) glucolipides, containing glucose. Galactolipides are the more abundant form; glucolipides were originally identified in spleen from Gaucher's disease, a condition in which excessive amounts of cerebrosides accumulate in the spleen, but are now known to be a normally occurring component of various tissues. Cerebrosides appear to be an important constituent of the myelin sheath of medullated nerve fibers, which contain about three times as much cerebroside as is found in nonmedullated nerves. The fatty acid in phrenosine is the hydroxy acid phrenosinic acid  $C_{24}H_{48}(OH)COOH$ , and in kerasine it is lignoceric acid. The glycolipides are relatively less soluble in ether and more soluble in hot alcohol than the phosphatides.

**GANGLIOSIDES.** Gangliosides represent a class of cerebrosides first described by Klenk, which are found in brain gray matter, spinal cord, and other tissues. On hydrolysis they yield one molecule each of a base, presumably sphingosine, stearic acid, neuraminic acid, and three molecules of galactose.

**SULFOLIPIDES (SULFATIDES).** The sulfolipides are similar to the cerebrosides, but characteristically contain sulfuric acid esterified with cerebronic (hydroxylignoceric) acid. Sulfolipides containing sphingosine, galactose, cerebronic acid, sulfuric acid and potassium in equimolecular proportions have been characterized by Blix.

**CHOLESTEROL.** Cholesterol, one of the primary cell constituents, is present in fairly large amount in nervous tissue. It is a monatomic alcohol containing one double bond, with the empirical formula  $C_{27}H_{45}OH$ . Its structure is as follows:

**Cholesterol**

The carbon atoms are numbered as shown for purposes of reference. The four rings A, B, C, and D form the cyclopentano-perhydrophenanthrene nucleus, which is characteristic not only of cholesterol and other plant and animal sterols but also of a wide variety of naturally occurring compounds of surprisingly diverse physiological significance. These compounds include (a) the bile salts, (b) the steroid hormones, (c) the sterol vitamins, (d) the aglycone portion of the cardiac glycosides (digitalis, etc.), (e) the sapogenins, derived from plant saponins; and one might also include here the carcinogenic hydrocarbons of the phenanthrene type. The possible interrelationship of these varied compounds, whose chemical structures are fundamentally similar, has attracted considerable attention; it has been shown for example that the cholesterol of the bile is a precursor of the chemically similar cholic acid derivatives also present.

Cholesterol is soluble in ether, chloroform, benzene, and hot alcohol. It crystallizes in the form of thin, colorless, transparent plates (see Fig. 101). Cholesterol is present in bile, and occurs abundantly in one form of biliary calculus. It is also present in blood and its quantitative determination is of clinical importance (see p. 580). It has been found in feces, wool fat, egg yolk, and milk, frequently in the form of its esters of higher fatty acids. It is found in the tissues of all animals. The cholesterol present in the animal body has its origin in animal foods or synthesis in the body; work with isotopes has shown that acetic acid may be a major intermediate in this synthesis. It does not appear to arise from plant sterols. That cholesterol may be synthesized in the animal body is proved by experimental work using isotopes as well as by such facts as that hens continue to lay eggs containing cholesterol when fed a cholesterol-free diet and that the tissues of the rat contain the usual cholesterol content when fed a diet containing no sterols.

Various isomers and derivatives of cholesterol are found in plant and animal tissues; only a few may be considered here. A further discussion of steroid isomerism will be found in Chapter 26. *Allocholesterol* or *coprostenol* is an isomer of cholesterol differing only in that the double bond is in the 4-5 instead of the 5-6 position. *Coprosterol* or *coprostanol* is formed by the addition of two hydrogen atoms at the double bond in allocholesterol. It is found in the feces, being formed by bacterial reduction. *Ergosterol* (a provitamin D) differs from cholesterol in having two more double bonds, one in the 7-8 position and one in the side chain, with an additional methyl group in the side chain which thus becomes  $-\text{CH}(\text{CH}_3)\cdot\text{CH}:\text{CH}\cdot\text{CH}(\text{CH}_3)\cdot\text{CH}(\text{CH}_3)\cdot\text{CH}_3$ . On suitable irradiation ergosterol finally yields *calciferol* with a rupture of the B ring. 7-Dehydrocholesterol, found in the skin, is also activated by irradiation to produce a compound with vitamin-D activity. *Stigmasterol* obtained from plant sources differs from ergosterol in having only one double bond in the nucleus (like cholesterol) and in having the second methyl group in the side chain replaced by an ethyl group. The *phytosterols* or plant sterols comprise several different sterols. According to Schoenheimer, the bulk of plant sterols do not appear to be absorbed by the body.

**Inorganic Salts.** Nervous tissue yields about 1 per cent of ash which is made up in large part of sodium and potassium chlorides and phos-

phates. The inorganic salts of fresh brain and nerve tissue consist largely of sodium and potassium chloride, potassium being in excess over sodium. The content of sodium and potassium ions varies from one part of the brain to another, and has attracted considerable attention in relation to a possible role in nerve action. The student is referred to Page's book for a further discussion of this subject (see Bibliography).

## CHEMICAL CHANGES IN NERVOUS ACTIVITY

The carbohydrate metabolism of nervous tissue appears to follow much the same course as that of muscle tissue, going by way of pyruvate and lactate anaerobically, and the *citric acid cycle* aerobically. Since glycogen is low in amount in the brain and glucose appears to be the major carbohydrate substrate, this organ is more immediately dependent upon the blood sugar supply. Nerves consume oxygen and liberate heat to a greater extent following stimulation.

The transmission of impulses along a nerve or from nerve fibers to muscle fibers or secretory cells, or from one nerve fiber to another across synapses in ganglia, is thought to involve chemical changes, either directly or as the source of potential differences. According to one view, the nerve action current results from a redistribution of diffusible ions between the center of the nerve and the periphery, taking place successively along the nerve fiber. This redistribution of ions may be under the control of chemical agencies.

At the motor nerve endings in voluntary muscle, stimulation appears to liberate the compound acetylcholine (see below). Involuntary muscles and secretory cells are controlled by two sets of nerves, sympathetic and parasympathetic. The parasympathetic fibers liberate acetylcholine at the nerve endings in such cells. Stimulation of such nerves causes smooth muscle fibers, as in blood vessels, to relax with dilation of the vessels. Stimulation of the sympathetic nerves brings about the liberation of at least two substances whose structures are known; these are adrenaline (epinephrine, suprarenine) and nor-adrenaline (nor-epinephrine, arterenol, demethylated epinephrine).

Usually only one of these two *neurohormones*, as they are called, predominates in a particular organ or extract thereof. There is some basis for the view that nor-adrenaline is a precursor of adrenaline. Of the two possible optical isomers of each compound, the levorotatory form is biologically much more active than is the dextrorotatory form.

Nerves which release adrenaline or nor-adrenaline on stimulation are known as adrenergic nerves; those releasing acetylcholine are called cholinergic nerves. The sympathetic fibers are adrenergic nerves; cho-

linergic nerves include motor nerves, all preganglionic fibers, and the postganglionic parasympathetic fibers.

**Acetylcholine.** As stated above, acetylcholine is believed to be the neurohormone of cholinergic nerves. Chemically, acetylcholine is the acetic acid ester of choline:

The structure as shown is that of the base; the compound is usually obtained commercially as a halogen salt, the iodide being less hygroscopic than the chloride or bromide. Solutions of acetylcholine salts show slight hydrolysis in neutral solution, which is accelerated in alkaline solution. Free acetylcholine may be detected, usually by bioassay, in low concentration in nervous and other tissues. A relatively much greater proportion of the total detectable acetylcholine content of tissues is in a bound inactive form. The acetylcholine released by nerve stimulation presumably comes from this source; the mechanism is not known.

Brain tissue contains an enzyme, choline acetylase, which promotes the synthesis of acetylcholine from choline and acetate, through the mediation of adenosinetriphosphate (ATP) and coenzyme A. This reaction is similar to other biological acetylations involving coenzyme A (see Chapter 33), choline acting as acceptor of the acetyl group.

Physiological control over the excessive accumulation of acetylcholine constantly being produced by normal nerve impulses appears to be effected by the enzyme cholinesterase, which catalyzes the hydrolysis of acetylcholine into the relatively inert compounds choline and acetic acid.

Cholinesterase activity is found in the nervous tissues of all animal species thus far studied; it is also present in mammalian red blood cells, blood plasma, to a certain extent in other tissues, and in snake venom. The cholinesterase activity of the brain varies with location, the caudate nucleus being much more active than other portions of the brain. The enzyme has not been obtained in a pure or crystalline form; the most potent preparations have been made by Nachmansohn from the electric organ of the electric eel.

Study of cholinesterase activity in various tissues has revealed that cholinesterase is not a single enzyme but rather a name for a group of enzymes of varying characteristics and biological significance. One classification groups the cholinesterases into two broad classes, the "true" cholinesterases and the "pseudo" cholinesterases. The "true" enzymes are represented by the cholinesterases of nervous tissue, red

blood cells, and the electric organ of the electric eel and similar marine species. The cholinesterases of the blood plasma of most (but not all) animal species and of tissues other than nervous tissue belong to the class of "pseudo" cholinesterases.

The two classes of cholinesterases are distinguishable from each other in terms of substrate specificity and biological occurrence and function. Thus, though both red cell ("true") and plasma ("pseudo") cholinesterase will act upon acetylcholine, other choline esters (propionylcholine, benzoylcholine) are much less readily hydrolyzed by the red-cell enzyme than is acetylcholine; whereas the reverse is true for the plasma enzyme, which will, for example, rapidly decompose benzoylcholine. Distinction between the two types of cholinesterases is frequently based upon such differences in substrate specificity. Furthermore, the function of the cholinesterase of nervous tissue appears to be understandable in relation to the production and disappearance of acetylcholine in nerve function, whereas the plasma enzyme is one of the plasma proteins whose precise physiological function is not yet clear.

Interest in cholinesterases has been heightened by the discovery that drugs of the physostigmine (eserine) class, together with certain commercially important insecticides, owe their mechanism of action to the ability to inactivate cholinesterase. Such anticholinesterase action can be demonstrated *in vivo* and *in vitro*. In the case of physostigmine, inactivation of the enzyme appears to be based upon competitive inhibition, the drug competing with acetylcholine for, and blocking it from, access to the enzyme molecule. This action is reversible in the laboratory by dialysis, enzymatic activity being restored when the drug is dialyzed away. In the case of patients, the cholinesterase activity of blood and tissues is lowered considerably after treatment with the drug, but returns to normal in a matter of hours.

An anticholinesterase drug which irreversibly<sup>1a</sup> inactivates cholinesterase is illustrated by the substance di-isopropylfluorophosphate (DFP).

**Di-isopropylfluorophosphate**  
(DFP)

DFP is about 100 times as effective as physostigmine in anticholinesterase potency *in vitro*; furthermore, the reaction of drug and enzyme is irreversible. It has been shown that DFP reacts directly with the enzyme through the P-F linkage, the F splitting off in the process and the remainder of the DFP molecule becoming attached to the enzyme, giving

<sup>1a</sup> Irreversible is used here in the sense that the inactivation cannot be reversed by dialysis, the drug being firmly bound to the enzyme. However, Wilson (*J. Biol. Chem.*, **190**, 111 (1951); *J. Am. Chem. Soc.*, **75**, 4628 (1953)) has shown that treatment of the inactive enzyme with solutions of hydroxylamine and similar compounds will lead to the gradual restoration of enzymatic activity *in vitro*. The bound inactivating drug is presumably split from the enzyme molecule by this treatment.

an enzymatically inactive product. Exactly how and why the DFP reacts with the polypeptide chain of the enzyme protein is not clear. Clinically, DFP is used in the treatment of glaucoma, paralytic ileus, and other conditions involving muscular dysfunction. Decrease in cholinesterase activity produced by DFP treatment in patients is much more prolonged than that produced by physostigmine, and essentially dependent upon the replacement of inactivated enzyme by new enzyme.

Insecticides whose mechanism of action is ascribed to anticholinesterase activity include the following:

**Tetraethyl pyrophosphate  
(TEPP)**

**Parathion**

**Octamethyl pyro-  
phosphoramide  
(OMPA)**

In the case of TEPP, insecticidal activity is due to a direct action on cholinesterase, TEPP being similar to DFP in this respect. Parathion does not have any significant anticholinesterase activity when quite pure; insecticidal activity may be due to impurities, or to metabolic conversion of the  $\text{P}=\text{S}$  bond to  $\text{P}=\text{O}$ , which produces a substance (Para-oxon) with strong anticholinesterase activity. OMPA is another example of a compound which has no anticholinesterase activity as such, but is converted by plant and animal tissues into a potent anticholinesterase, probably by oxidation within the cell, although the chemical nature of the reaction is not yet entirely clear.

## EXPERIMENTS ON THE LIPIDES OF NERVOUS TISSUE

**1. Preparation of Pure Lecithin.**<sup>2</sup> Free 4 pounds of brain tissue from adhering foreign tissue and mince in a chopping machine. Dry in a vacuum drying oven. (If such an oven is not available dry the tissue by treating several times with cold acetone.) Extract twice with acetone, using about 1.6 liters. Extract the residue with 2.4 liters of hot alcohol. Concentrate to one-third the original volume. Put in the refrigerator at  $0^\circ\text{C}$ . overnight. Filter. To the filtrate add a cold saturated solution of cadmium chloride sufficient to completely precipitate the lecithin.

To avoid decomposition in purification do not use high temperatures when effecting solution or concentration, and reduce the use of water to a minimum. The principal impurity in the cadmium precipitate is cephalin.

<sup>2</sup> The preparation from egg yolk is somewhat simpler. Stir the fresh egg yolks to a homogeneous emulsion with an egg-beater. Strain through cheesecloth. Pour into a double volume of hot 95 per cent alcohol. Allow to cool. Precipitate with cadmium chloride and purify as indicated above.

To remove this, shake the salts well with ether, and centrifuge. Repeat 8 to 10 times. Suspend 10 g. of the salts in 40 ml. of chloroform, and shake at room temperature until a slightly opalescent solution is formed. Add a cold 25 per cent solution of ammonia gas in 95 per cent methyl alcohol as long as a precipitate is formed, avoiding a large excess. Centrifuge. Concentrate at about 10 to 15 mm. pressure on a water bath at 35° to 40° C. Dissolve in dry ether and concentrate as before to get rid of moisture. Repeat. Dissolve in a minimum amount of ether and pour into acetone (about 50 ml.). Decant. Dry the residue in a vacuum desiccator over  $\text{H}_2\text{SO}_4$  and keep in a sealed glass tube to prevent oxidation.

**2. Preparation of Crude Lecithin.**<sup>3</sup> Treat the finely divided brain of a sheep or a rabbit with enough ether to cover well, and allow it to stand in the cold for 48 to 72 hours. The cold ether will extract lecithin and cholesterol. Filter and add two volumes of acetone to the filtrate to precipitate the lecithin. Filter off the lecithin, saving the filtrate for the preparation of cholesterol (see below) if desired. Test the lecithin as follows:

(a) MICROSCOPICAL EXAMINATION. Suspend a small portion in a drop of water on a slide and examine under the microscope. Do you see any "myelin forms"?

(b) OSMIC ACID TEST.<sup>4</sup> Treat a small portion with osmic acid. What happens? Why?

(c) ACROLEIN TEST. Make the acrolein test according to the directions on p. 106.

(d) TEST FOR PHOSPHORUS. See p. 212.

**3. Preparation of Cephalin.** Free 4 pounds of brain tissue from membranes, mince in a hashing machine, and dry in a vacuum drier. Pulverize and dry further. Extract exhaustively with acetone, using about 2 liters. Free from acetone in the vacuum drier and extract with about 3 liters of 95 per cent alcohol. Extract the residue with 2 liters of ether. Concentrate to a small volume. Let stand at 0° C. over night. Centrifuge and pour supernatant liquid into 98.5 per cent alcohol warmed to 60° C. Dissolve the precipitate in ether. Allow it to stand at 0° C. over night. Repeat the precipitation with alcohol, redissolving in ether until on standing the ethereal extract no longer deposits a sediment of white matter. The final precipitate is dried and preserved as for lecithin.

**4. Preparation of Cholesterol.**<sup>5</sup> Place a small amount of finely divided brain tissue under ether and stir occasionally for one hour. Filter, evaporate the filtrate to dryness on a water bath, and test the cholesterol according to the directions given below. (If it is desired, the ether-acetone filtrate from the lecithin may be used for the isolation of cholesterol. In these cases it is simply necessary to evaporate the solution to dryness on a water bath.) Upon the cholesterol prepared by either of the above methods make the following tests:

(a) MICROSCOPICAL EXAMINATION. Examine the crystals under the microscope and compare them with those in Fig. 101.

(b)  $\text{H}_2\text{SO}_4$  TEST (SALKOWSKI). Dissolve a few crystals of cholesterol in a little chloroform and add an equal volume of concentrated sulfuric acid. A play

<sup>3</sup> The lecithin prepared in this way is satisfactory for the qualitative tests.

<sup>4</sup> Osmic acid serves to detect fats which contain unsaturated fatty acid radicals—e.g., oleic acid—in their molecule.

<sup>5</sup> Pure cholesterol may be prepared from gallstones. Extract with benzene. Evaporate. Recrystallize from alcohol.

of colors from bluish-red to cherry-red and purple is noted in the chloroform, while the acid assumes a marked green fluorescence.

(c) ACETIC ANHYDRIDE- $\text{H}_2\text{SO}_4$  TEST (LIEBERMANN-BURCHARD). Dissolve a few crystals of cholesterol in 2 ml. of chloroform in a dry test tube. Now add 10 drops of acetic anhydride and 1 to 3 drops of concentrated sulfuric acid. The solution becomes red, then blue, and finally bluish-green in color.

(d) FORMALDEHYDE- $\text{H}_2\text{SO}_4$  TEST. To 2 ml. of a chloroform solution in a dry test tube add 2 ml. of formaldehyde- $\text{H}_2\text{SO}_4$  solution (1 part of 40 per cent formaldehyde to 50 of the acid). Note the cherry color in the chloroform. Pour off the chloroform into another tube and add 2 to 3 drops of acetic anhydride. Note the blue color. This test is said to be more delicate than Sal-kowski's test.

**5. Preparation of Glycolipide.** Mince 100 g. of sheep brains. Transfer to a 500-ml. flask and add slowly with shaking 200 ml. of alcohol. Heat on a water bath for one hour with occasional shaking. Filter hot. Treat the residue on the water bath with another 100 ml. of alcohol for 15 minutes. Filter, and combine the filtrates. Let stand over night. Filter off the precipitate on a small paper. Transfer the paper to a beaker containing 50 ml. of hot alcohol. Stir to dissolve the lipide and filter hot. Let cool. Filter or centrifuge, and wash the precipitate with ether to remove cholesterol. The residue consists mainly of the glycolipides phrenosin and kèrasin.

(a) MICROSCOPICAL EXAMINATION. Suspend a small portion in a drop of water on a slide and examine under the microscope.

(b) SOLUBILITY. Try the solubility of the glycolipide in water, and in dilute acid and alkali, and in hot and cold alcohol and hot and cold ether.

(c) PHOSPHORUS. Test for phosphorus according to the directions on p. 212. How does the result compare with that obtained with lecithin?

(d) Place a little glycolipide on platinum foil and warm. Note the odor.

(e) HYDROLYSIS OF GLYCOLIPIDE. Place the remaining glycolipide in a small evaporating dish, add equal volumes of water and dilute hydrochloric acid, and boil for one hour. Cool, neutralize with solid sodium carbonate, filter, and test with Benedict's solution. Is there any reduction, and if so how do you explain it?

## 6. Tests for Choline.

(a) ROSENHEIM'S PERIODIDE TEST. Prepare an alcoholic extract of the fluid under examination, and after evaporation apply Rosenheim's iodo-potassium iodide solution<sup>6</sup> to a little of the residue. In a short time, dark brown plates and prisms of choline periodide begin to form and may be detected by means of the microscope. Occasionally they are large enough to be visible to the naked eye. They somewhat resemble crystals of hemin (see p. 483). If the slide be permitted to stand, thus allowing the fluid to evaporate, the crystals will disappear and leave brown oily drops. They will reappear, however, upon the addition of fresh iodine solution. v. Staněk claims that this choline compound has the formula  $\text{C}_5\text{H}_{14}\text{NOI}\cdot\text{I}_8$ .

(b) ROSENHEIM'S BISMUTH TEST. Extract the fluid under examination with absolute alcohol, evaporate, and re-extract the residue. Repeat the extraction several times. Dissolve the final residue in 2 to 3 ml. of water and add a drop of Kraut's reagent.<sup>7</sup> Choline is indicated by the appearance of a bright brick-red precipitate.

<sup>6-7</sup> See Appendix.

## Enzymes and Their Action: Cell Respiration

The myriad chemical transformations going on continually in living matter would not be possible without enzymes, which are the most important tools of the living cell. For the hydrolysis or the oxidation of such substances as fats and proteins, in the laboratory we commonly employ strong acids or alkalies or oxidizing agents and high temperatures. Such reagents and temperatures are incompatible with the existence of living matter. The cells are, however, able to carry out such reactions at approximate neutrality, at body temperatures, and at high speed with the aid of enzymes. As an example it has been shown that it takes 10,000,000 times as great a concentration of hydrogen ion as of the enzyme sucrase to decompose a given amount of cane sugar in a given time at body temperature.

Enzymes are organic catalysts produced by living organisms. They are generally soluble and colloidal substances, characterized by great activity, specificity, and susceptibility to the influence of pH, of temperature, and of other environmental changes.

**Catalysis.** As indicated, enzymes act catalytically. Catalysts are substances that alter the speed of chemical reactions without themselves undergoing any permanent change. This definition indicates that catalysts do not initiate chemical reactions but only speed up reactions already proceeding at a slow rate. Thus hydrogen peroxide undergoes a very slow spontaneous decomposition at room temperature with the formation of water and oxygen. The addition of a little finely divided platinum or of an enzyme called catalase enormously increases the rate of this decomposition. Catalysts function in many reactions, however, which cannot definitely be shown to be proceeding in their absence. It may be assumed in these cases that the reaction is actually proceeding but at an immeasurably slow rate. From the practical standpoint, however, the catalyst or enzyme in these cases does initiate a reaction.

Inorganic catalysts are of great importance in industry. Thus sulfur dioxide reacts slowly with oxygen to form sulfur trioxide. If, however, oxides of nitrogen are present, they catalyze the reaction so that it proceeds much more rapidly, e.g.,

Further analogies between enzymes and inorganic catalysts will be mentioned later.

**Classification.** All the enzymes which have been isolated in pure condition to date are proteins. The properties which are used to classify proteins are much too general to be of use in classifying enzymes. Hence it is customary to classify them according to their action. Some enzymes contain characteristic prosthetic groups conjugated with the protein, and these groups are also used for further classification. For example, oxidizing enzymes are commonly subdivided according to whether they contain heme, riboflavin, etc., as prosthetic groups. A considerable number of enzymes can be classified under the general term *transferases* since their action is to transfer such groups as amino, methyl, acetyl, glucosyl, fructosyl, or phosphoryl from one compound to another.

**HYDROLASES.** A great many enzymes catalyze hydrolysis reactions. This large group is commonly designated as hydrolases. The hydrolases, like other enzymes, are further classified according to their substrates, i.e., the substances on which they act. The nomenclature is harmonized as far as possible by using the termination *ase* in the names of enzymes. Thus we have esterases hydrolyzing esters, carbohydrases hydrolyzing carbohydrates, proteinases hydrolyzing proteins, amidases hydrolyzing amides, etc. Under each of these groups are individual enzymes which act on specific substrates, such as maltase which splits maltose, lactase which hydrolyzes lactose, etc. The source of the enzyme may also be indicated in its name, such as salivary amylase, pancreatic lipase, etc. Some of the old names for enzymes are still used as a matter of convenience—such names, for example, as pepsin and trypsin.

**OXIDIZING ENZYMES.** Another large group of enzymes catalyzes oxidations. These may be called oxidizing enzymes. Oxidizing enzymes are frequently divided into two groups—oxidases and dehydrogenases—which are distinguished by their mode of action. This is not an entirely satisfactory division since some enzymes can be placed in either group. A more suitable classification makes no attempt to distinguish between oxidases and dehydrogenases—other criteria are used instead. For example, the following groups may be recognized: (1) Enzymes containing iron, (2) enzymes containing copper, (3) enzymes containing coenzymes I or II, (4) enzymes which catalyze the reduction of cytochrome, (5) enzymes which contain riboflavin (yellow enzymes), and (6) various other oxidizing enzymes.

There are still other enzymes that do not fit into either of these groups. For example, phosphorylases act similarly to hydrolases, except that a phosphoric acid residue, and not water, is used in splitting the substrate. There are other enzymes, the hydrases, which remove or add water to the substrate without hydrolyzing it, and there are still other enzymes, the true desmolases, which catalyze the splitting of a carbon chain. Thus, zymohexase catalyzes the reversible splitting of fructose-1,6-diphosphate into the triosephosphates, dihydroxyacetone phosphate and phosphoglyceric aldehyde. The mutases catalyze the oxidation of one molecule of the substrate and the simultaneous reduction of another molecule of the substrate. Recently aldehyde mutase has been shown by Racker to be nothing more than a mixture of alcohol dehydrogenase and aldehyde dehydrogenase.

In a number of cases, two or more names are commonly applied to the same enzyme. For example, amylase is also known as diastase; sucrase is commonly called invertase or saccharase; cytochrome oxidase was formerly called indophenol oxidase, etc. Sometimes such synonyms arose because enzymes from different sources at first were not recognized to be identical. For example, tyrosinase or monophenoloxidase was at one time thought to be distinct from polyphenoloxidase. In other cases the original name given to an enzyme has proved to be inadequate. For example, the name zymase was at one time used for the yeast enzyme which ferments sugars to alcohol. Subsequently it was found that the original zymase was really several enzymes and the original name had to be discarded.

A list of some of the more important enzymes is given in this connection, without any attempt to adhere to a rigid classification (see Table, pp. 306–307).

**Chemical Nature.** The problem of the purification of enzymes has been essentially one of their separation from other associated proteins. Because of the difficulties of such separation and purification, the chemical nature of enzymes has been much in doubt. The first preparation of a crystalline enzyme was that of urease by Sumner in 1926 (see Fig. 75). Since that time crystalline pepsin was obtained by Northrop (see Fig. 76), crystalline trypsin and chymotrypsin by Northrop and Kunitz, and pepsinogen by Herriott and Northrop. Crystals of yellow respiratory ferment were obtained by Warburg, and those of  $\beta$ -amylase (Fig. 74) by Balls. To date, about 60 enzymes have been obtained in crystalline form. However, a few of the claims made are either erroneous or dubious. All of these crystalline preparations have proved to be proteins, and the specific action of these enzymes has never been observed in the absence of the specific proteins. There is additional evidence which shows rather clearly that the enzymes and crystalline proteins are identical. If the protein is destroyed or denatured, the enzyme action is lost. Also, various crystalline enzyme preparations have been tested for homogeneity, using such criteria as diffusion, movement in an ultracentrifuge, migration in an electrical field, solubility, etc.; and with the exception of pepsin each has been found to consist of a single component. Pepsin appears to be a mixture of similar proteins. Some of these crystalline enzymes have been recrystallized as many as ten times without change in composition and properties.

Further evidence that the enzyme itself is a protein has been presented, as in the case of pepsin, by showing that if the protein of the material is denatured through the action of alkali, the activity of the enzyme is decreased in a parallel manner. For example, pepsin becomes completely denatured and inactive at pH 10.5. If the solution is adjusted to pH 5.4 and is allowed to stand at this pH, a small part of the protein is renatured and there is a corresponding appearance of activity of the enzyme. The solution should be adjusted to about pH 1 before testing for the enzyme activity.

Crystalline trypsin denatured by heat also shows on standing a parallel reappearance of activity and of native protein in the solution. The trypsin

## CLASSIFICATION OF ENZYMES

| <i>Name and Class</i>                                          | <i>Distribution</i>                                         | <i>Substrate</i>                                                              | <i>End-products</i>                              |
|----------------------------------------------------------------|-------------------------------------------------------------|-------------------------------------------------------------------------------|--------------------------------------------------|

| 1. Polynucleotidase.....                                       | Pancreatic juice, intestinal juice, etc.                    | Nucleic acid.....                                                             | Nucleotides                                      |
| 2. Nucleotidase.....                                           | Intestinal juice, and other tissues                         | Nucleotides.....                                                              | Nucleosides and phosphoric acid                  |
| 3. Nucleosidase.....                                           | Animal tissues.....                                         | Nucleosides.....                                                              | Carbohydrate and bases                           |
| <i>Amidases</i> .....                                          | .....                                                       | Amino compounds and amides                                                    |                                                  |
| 1. Arginase.....                                               | Liver.....                                                  | Arginine.....                                                                 | Ornithine and urea                               |
| 2. Urease.....                                                 | Bacteria, soybean, jack bean, etc.                          | Urea.....                                                                     | Carbon dioxide and ammonia                       |
| 3. Glutaminase.....                                            | Liver, etc.....                                             | Glutamine.....                                                                | Glutamic acid and ammonia                        |
| 4. Transaminase.....                                           | Animal tissues.....                                         | Glutamic acid and oxalacetic acid, etc.                                       | $\alpha$ -Ketoglutaric acid, aspartic acid, etc. |
| <i>Purine Deaminases</i> .....                                 | .....                                                       | Purine bases and derivatives                                                  |                                                  |
| 1. Adenase.....                                                | Animal tissues.....                                         | Adenine.....                                                                  | Hypoxanthine and ammonia                         |
| 2. Guanase.....                                                | Animal tissues.....                                         | Guanine.....                                                                  | Xanthine and ammonia                             |
| <i>Peptidases</i> .....                                        | .....                                                       | Peptides                                                                      |                                                  |
| 1. Aminopolypeptidase...                                       | Yeast, intestines, etc.                                     | Polypeptides.....                                                             | Simpler peptides and amino acids                 |
| 2. Carboxypeptidase.....                                       | Pancreas.....                                               | Polypeptides.....                                                             | Simpler peptides and amino acids                 |
| 3. Dipeptidase.....                                            | Plant and animal tissues and bacteria                       | Dipeptides.....                                                               | Amino acids                                      |
| 4. Prolinase.....                                              | Animal tissues and yeast                                    | Proline peptides.....                                                         | Proline and simpler peptides                     |
| <i>Proteinases</i> .....                                       | .....                                                       | Proteins                                                                      |                                                  |
| 1. Pepsin.....                                                 | Gastric juice.....                                          | Proteins.....                                                                 | Proteoses, peptones, etc.                        |
| 2. Trypsin.....                                                | Pancreatic juice.....                                       | Proteins, proteoses, and peptones                                             | Polypeptides and amino acids                     |
| 3. Cathepsin.....                                              | Animal tissues.....                                         | Proteins.....                                                                 | Proteoses and peptones                           |
| 4. Rennin.....                                                 | Calf stomach.....                                           | Casein.....                                                                   | Paracasein                                       |
| 5. Chymotrypsin.....                                           | Pancreatic juice.....                                       | Proteins, proteoses, and peptones                                             | Polypeptides and amino acids                     |
| 6. Papain.....                                                 | Papaya, other plants                                        | Proteins, proteoses, and peptones                                             | Polypeptides and amino acids                     |
| 7. Ficin.....                                                  | Fig sap.....                                                | Proteins                                                                      | Proteoses, etc.                                  |
| <i>Esterases</i> .....                                         | .....                                                       | Esters.....                                                                   | Alcohols and acids                               |
| 1. Lipase.....                                                 | Pancreas, castor bean, etc.                                 | Fats.....                                                                     | Glycerol and fatty acids                         |
| 2. Esterases.....                                              | Liver, etc.                                                 | Ethyl butyrate, etc.                                                          | Alcohols and acids                               |
| 3. Phosphatases.....                                           | Plant and animal tissues                                    | Esters of phosphoric acid                                                     | Phosphate and alcohol                            |
| 4. Sulfatases.....                                             | Animal and plant tissues                                    | Esters of sulfuric acid                                                       | Sulfuric acid and alcohol                        |
| 5. Cholinesterase.....                                         | Blood, tissues.....                                         | Acetylcholine.....                                                            | Choline and acetic acid                          |
| <i>Iron Enzymes</i>                                            |                                                             |                                                                               |                                                  |
| 1. Catalase.....                                               | All living organisms except a few species of microorganisms | Hydrogen peroxide...                                                          | Water and oxygen                                 |
| 2. Cytochrome oxidase...                                       | All living organisms except a few species of microorganisms | Reduced cytochrome C in the presence of oxygen                                | Oxidized cytochrome C and water                  |
| 3. Peroxidase.....                                             | Nearly all plant cells                                      | A large number of phenols, aromatic amines, etc., in the presence of $H_2O_2$ | Oxidation product of substrate and water         |
| <i>Copper Enzymes</i>                                          |                                                             |                                                                               |                                                  |
| 1. Tyrosinase (polyphe-<br>noloxidase, monophe-<br>noloxidase) | Plant and animal tissues                                    | Various phenolic compounds                                                    | Oxidation product of substrate                   |
| 2. Ascorbic acid oxidase..                                     | Plant tissues.....                                          | Ascorbic acid in the presence of oxygen                                       | Dehydroascorbic acid                             |

CLASSIFICATION OF ENZYMES—(Continued)

| Name and Class                                     | Distribution                                 | Substrate                                                   | End-products                                                                                              |
|----------------------------------------------------|----------------------------------------------|-------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------|
| <b>Enzymes Containing Co-enzymes I and/or II</b>   |                                              |                                                             |                                                                                                           |
| 1. Alcohol dehydrogenase                           | Animal and plant tissues                     | Ethyl alcohol and other alcohols                            | Acetaldehyde and other aldehydes                                                                          |
| 2. Malic dehydrogenase..                           | Animal and plant tissues                     | L(–) Malic acid .....                                       | Oxalacetic acid                                                                                           |
| 3. Isocitric dehydrogenase                         | Animal and plant tissues                     | L-Isocitric acid .....                                      | Oxalosuccinic acid                                                                                        |
| 4. Lactic dehydrogenase..                          | Animal tissues and yeast                     | Lactic acid.....                                            | Pyruvic acid                                                                                              |
| 5. β-Hydroxybutyric dehydrogenase                  | Liver, kidneys, and heart                    | L-β-Hydroxybutyric acid                                     | Acetoacetic acid                                                                                          |
| 6. Glucose dehydrogenase                           | Animal tissues.....                          | D-Glucose.....                                              | D-Gluconic acid                                                                                           |
| 7. Robison ester dehydrogenase                     | Erythrocytes and yeast                       | Robison ester (hexose-6-phosphate)                          | Phosphohexonic acid                                                                                       |
| 8. Glycerophosphate dehydrogenase                  | Animal tissues.....                          | Glycerophosphate....                                        | Phosphoglyceric acid                                                                                      |
| 9. Aldehyde dehydrogenase                          | Liver.....                                   | Aldehydes.....                                              | Acids                                                                                                     |
| <b>Enzymes Which Reduce Cytochrome</b>             |                                              |                                                             |                                                                                                           |
| 1. Succinic dehydrogenase (as ordinarily prepared) | Plants, animals, and microorganisms          | Succinic acid.....                                          | Fumaric acid                                                                                              |

| 4. Phosphoglucomutase..                            | Plants and animals....                       | Glucose-1-phosphate                                         | Glucose-6-phosphate                                                                                       |

may also be hydrolyzed by pepsin in acid solution, and the loss in activity is just proportional to the hydrolysis of the trypsin protein.

In the case of those crystalline enzymes which have been most studied it seems clear that the enzyme activity is bound up with the integrity of the protein of the preparation and that these enzymes are thus properly

characterized as proteins. Experiments by Northrop on the acetylation of pepsin suggest that the activity is bound up, not with the primary amino groups, but with the presence of free hydroxyl groups of tyrosine. That certain enzymes may owe their activity to groups of a nonprotein character combined with protein is clear from our knowledge of the oxidases, some of which appear to be heme-protein derivatives, the activity

of which is bound up with the iron-pyrrole group. Peroxidase is a specific example of such an oxidase. Heme has, however, much less peroxidase activity than its natural protein combinations, so that both elements are evidently essential for proper function. Preparations of certain other enzymes—such as amylase, sucrase, and lipase—have been variously reported as protein-free or very low in protein. Protein tests made on enzyme solutions are, however, inconclusive, since the protein tests are far less sensitive than the tests for enzyme activity. As to the nature of the groups in the enzyme molecules which are responsible for the specificity of their action, almost nothing is known except in the cases of some of the oxidases.

**Specificity and Mechanism of Enzyme Actions.** Not only do proteinases not act upon carbohydrates, nor carbohydrases upon proteins, but much greater degrees of specificity exist. Thus maltose, lactose, and sucrose require different enzymes for their hydrolysis. Further, the maltase of yeast splits maltose (an  $\alpha$ -glucoside) and certain other  $\alpha$ -glucosides, but not  $\beta$ -glucosides; but  $\beta$ -glucosidase or emulsin hydrolyzes only  $\beta$ -glucosides. The maltase will not hydrolyze any glucosides in which the  $\alpha$ -glucose residue has been altered. The specificity appears to depend primarily on the glucose residue and secondarily on the group attached to it. The dependence of enzyme action on the configuration of the substrate is further brought out by the fact that dipeptidase will attack glycyl-L-leucine but not glycyl-D-leucine. It was findings of this sort that led Emil Fischer to suggest that the relation of enzyme to substrate was much like that of a key to a lock.

It has been pointed out that enzymes are catalysts. Our knowledge of the mechanisms involved in enzymic catalyses is, however, very slight. There is much evidence that enzymes form intermediate compounds with the substrates on which they act. This intermediate compound is believed to be much less stable than the original substrate so that the latter now breaks down spontaneously, the enzyme being again liberated. According to the views of some workers there may be two groups (or perhaps more) in the enzyme which are involved, one group acting chiefly to bind the enzyme with the substrate while the second combines with another part of the substrate so as to reduce the stability of the substrate. This view has been developed especially in connection with the peptidases.

Intestinal dipeptidase will split all peptides made up of naturally occurring amino acids. It will not split peptides containing the optical isomers of these amino acids. Thus glycyl-L-leucine will be split but not glycyl-D-leucine. If the free carboxyl group of the dipeptide is esterified (as by making the ethyl ester), hydrolysis still occurs, indicating that the enzyme does not combine with the carboxyl group. If the free amino group is acetylated, the compound is not split. This indicates that the enzyme combines with the amino group of the peptide. If the H of the NH group of the peptide is substituted, it is not acted upon. Replacement of the H of the adjacent C atoms also prevents splitting.

These observations indicate that the enzyme must have at least four groups showing a similar space relationship to these four groups in the dipeptide. It has been suggested further that the enzyme combines with

rise in temperature. The optimum temperature for the action of an enzyme is thus determined by the balance between increase of activity with temperature and decrease in amount of enzyme present due to inactivation. In prolonged experiments, enzyme destruction becomes more important than in short experiments, and the optimum temperature for such experiments is therefore lower. The majority of enzymes act most rapidly at 40° to 50° C. For certain plant proteinases the optimum is higher.

**Influence of Hydrogen-ion Concentration.** Enzymes are inactivated by certain degrees of acidity or alkalinity. Thus yeast sucrase is inactivated rapidly below pH 3 and pepsin above pH 8. By the optimum pH of an enzyme is meant the pH at which it shows greatest activity. For most enzymes this point lies between pH 4 and 8, and for many between pH 5 and 7. For practically all enzymes the pH range is rather narrow and activity falls off rapidly on both sides of the optimum. The best pH depends to some extent on temperature and enzyme and substrate concentrations. The nature of the buffer may change the optimum pH of an enzyme considerably. The same is true for the nature of the substrate. When the substrates are ionizable, as in the case of proteins, the optimum pH may vary with the substrate. This is true for pepsin. One of the lowest pH optima is that for pepsin (pH 2); and one of the highest, that for blood phosphatase (pH 9). Alterations in pH may affect the dispersion of the enzyme, the rapidity of combination of enzyme and substrate, and the decomposition of the enzyme-substrate complex with the formation of reaction products.

**Influence of Other Physical Agents.** Enzymes may be destroyed by shaking, by ultraviolet irradiation, and by x-rays. These agents probably act by denaturing the enzyme.

**Influence of Chemical Agents.** Most enzymes when acting at optimum temperatures will show, on the addition of chemical agents, either an inhibiting effect or no effect at all. In some cases, however, an acceleration is noted, and certain enzyme preparations are inactive unless additions are made.

If salivary amylase is dialyzed free from NaCl, it becomes inactive on starch, but activity is restored on the addition of sodium, potassium, or certain other chlorides. The chloride here may be called a coenzyme; i.e., it belongs to a class of substances which are specific for particular enzymes and necessary for the activity of those enzymes. In this sense, phosphate, which is essential for the action of zymase, is also a coenzyme, as is the organic crystalloidal substance cozymase which is also necessary for zymase action. More recent usage limits the term coenzyme to organic compounds which act in this manner, e.g., diphosphopyridine nucleotide.

Many enzymes are activated by such metallic ions as  $Mg^{++}$ ,  $Co^{++}$ ,  $Mn^{++}$ ,  $Zn^{++}$ , etc. Emil Smith<sup>1</sup> has studied the activation of various peptidases and believes that at least two of the bonds between substrate and enzyme are through the metallic ion.

---

<sup>1</sup> Sumner and Myrbäck: *The Enzymes*, New York, Academic Press Inc., 1950, Vol. 1, Part 2, p. 793.

Activators and kinases are believed to bring about chemical changes in the inactive forms of enzymes, so as to render them active. Thus HCl changes inactive pepsinogen to active pepsin. The pepsinogen here is called a *zymogen* or *proenzyme*, and the HCl (or more strictly the H ion) is spoken of as an activator. Activators of an organic character are sometimes called kinases. Thus trypsinogen is changed to active trypsin by enterokinase. Enterokinase is probably an enzyme. It can be replaced by trypsin; the action of trypsin upon trypsinogen, therefore, is autocatalytic. Chymotrypsinogen and procarboxypeptidase also are activated by trypsin.

Enzymes are poisoned by a variety of substances which form compounds with them. A number of heavy metals stop enzyme action, apparently by combining with the enzyme acting as an acid, though combination with sulfhydryl groups in enzymes may also be involved. Urease is sensitive to traces of heavy metals. H<sub>2</sub>S may combat this toxicity of the heavy metals, probably by combining with them.

HCN and H<sub>2</sub>S have little effect on most hydrolytic enzymes. The proteinase called papain is, however, activated by them, and the action of keratinase is much facilitated by the presence of H<sub>2</sub>S. Certain oxidases are inactivated by these substances in small amounts, apparently because they combine with the active iron of these enzymes.

Certain acids, such as phosphotungstic or picric acid, combine with the enzyme, acting as a base, to form inactive compounds.

Antienzymes include various naturally occurring inhibitors with some degree of specificity. The blood serum contains antitrypsin, and the mucosa of the intestinal tract appears to contain some antipepsin and antitrypsin. In addition there are various antienzymes which are true immune bodies produced by the usual methods for producing antibodies. For example, antiluciferase, antiurease, and anticatalase have been produced by injecting the appropriate enzymes into animals.

**Kinetics of Enzyme Action.** Enzyme kinetics deals with the velocity of enzyme reactions and with agents or factors which affect this velocity.

It is usually possible to cause the velocity of an enzyme-catalyzed reaction to remain constant for a sufficient period of time to allow measurement of the enzyme by determining the reaction rate, if enough substrate is used and if other factors such as pH, temperature, etc. are held reasonably constant. A reaction of this variety is called one of apparent zero order and follows an equation of the form

$$(1) \quad \frac{x}{t} = k \quad \text{or}$$

$$(1a) \quad x = kt$$

where  $x$  is the amount of substrate decomposed in time  $t$ ,  $\frac{x}{t}$  is the reaction velocity, and  $k$  is a constant depending upon the amount of enzyme present. Provided that factors such as pH and temperature are held constant,  $k$  can be used as a measure of the amount of enzyme present.

If the amount of substrate employed is low, as is necessary with enzymes such as catalase which are gradually destroyed by excess sub-

strate, the reaction velocity is often proportional to the amount of substrate present at any time. Such a reaction is called an apparent monomolecular or first-order reaction and follows the equation

$$(2) \quad v = \frac{dx}{dt} = k(A - x)$$

(deduced from simple application of the mass law) where the velocity  $v$  must be expressed using the calculus notation  $\frac{dx}{dt}$  instead of  $\frac{x}{t}$ , since  $v$  varies continuously with  $x$ . The term  $A$  signifies the initial concentration of substrate;  $x$  is the decrease in concentration of substrate (equivalent to the increase in concentration of products) that has occurred at time  $t$ ; and  $k$  is a constant which varies with the amount of enzyme (at constant pH, temperature, etc.) and can be used as a measure of the amount of enzyme present.

Since Equation (2) is not applicable as it stands, it must be transformed by use of the integral calculus to eliminate the  $\frac{dx}{dt}$  term. When this is done the following equation is obtained:

$$(3) \quad \log \frac{A}{(A - x)} = kt, \quad \text{or}$$

$$(3a) \quad k = \frac{1}{t} \log \frac{A}{(A - x)}$$

If it is desired to obtain the theoretical initial reaction velocity, this can be done by multiplying  $k$  by  $A$ , or

$$v_i = kA$$

as is apparent from an inspection of Equation (2).

The use of the term *apparent* in describing the order of enzyme-catalyzed reactions is necessary because such reactions usually consist of a sequence of bimolecular reactions, one of which may be rate-limiting and therefore control the observed kinetics. In case water is involved in a rate-limiting bimolecular step, a truly bimolecular reaction will follow monomolecular kinetics, as is explained in texts on physical chemistry, owing to the essentially constant water concentration. Bimolecular kinetics are observed with only a few enzymic reactions and will not be considered here.

In case the concentration of substrate is neither very high nor very low, the observed kinetics of an enzyme-catalyzed reaction may not follow either an apparent zero-order or an apparent first-order reaction. In such a case it is still possible to obtain a valid measure of the amount of enzyme present from kinetic studies if one can measure the length of time necessary to attain decomposition of a certain fixed percentage of the substrate (say 5 per cent). In this case the amount of enzyme is proportional to the reciprocal of the time value.

As has been inferred above, the rate of an enzyme-catalyzed reaction

can be affected by factors such as change in temperature, change in pH, and change in substrate concentration (or partial pressure, if a gas is reacting). In addition the enzyme may be inactivated by the substrate or inhibited by various types of enzyme inhibitors.

Temperature change generally results in a bell-shaped curve when enzyme activity is plotted against temperature, with a pronounced optimum. The latter results from an enhancement of reaction rate as the temperature increases, followed eventually by a decrease in rate owing to the denaturation or destruction of the enzyme at higher temperature values. The exact position of the temperature optimum is not of theoretical significance however, since it is dependent upon various factors such as substrate concentration, pH, and the time interval during which the measurement of activity is carried out. It is very difficult to arrive at a good estimate of the initial reaction velocity in determining temperature optima. Hence a somewhat better procedure is to determine the effect of temperature on the enzyme by treating it at various temperatures for a given length of time and then determining activity under standard conditions of pH, temperature, and substrate concentrations. By this procedure an S-shaped curve is obtained which gives a more reproducible measure of the destructive effect of temperature on the enzyme. The effect of temperature on enzymatic activity is of theoretical significance (in calculating energy of activation) in the range where no damage to the enzyme is occurring, and throughout this range enzyme activity generally increases with temperature increase in a predictable way.

Curves showing the effect of pH on enzyme activity in general give optima which are of theoretical significance. Changes in pH may affect primarily the substrate or the enzyme, or both, and are concerned with producing the necessary ionic states of the enzyme or substrate or both.

A fundamental approach to enzyme kinetics was developed by Michaelis and Menten<sup>2</sup>, who proposed to measure the affinity of an enzyme for its substrate by studying the effect of substrate concentration on initial reaction velocity with a constant amount of enzyme present. The theoretical treatment is based upon the assumption of the following sequential reactions involving enzyme, substrate, and reaction products:

where  $E$  stands for enzyme,  $S$  for substrate, and  $P$  for products. The  $k$ 's are the rate constants for the reactions as indicated by the arrows.

In the simplest case it is assumed that the rate-limiting reaction is  $ES \rightarrow E + P$ , the formation of  $ES$  being much more rapid. By a simple algebraic process, if this assumption is made, the following equation can be derived, which shows the relation between the maximum reaction velocity  $V_m$ , obtained when an excess of substrate is present and the enzyme is saturated with substrate, and the reaction velocity  $v_i$  obtained with substrate concentrations below the saturation level:

<sup>2</sup> Michaelis and Menten: *Biochem. Z.*, **49**, 333 (1913).

$$(5) \quad v_i = \frac{V_m[S]}{[S] + K_m} \quad \text{or solving for } K_m,$$

$$(5a) \quad K_m = [S] \frac{V_m - v_i}{v_i}$$

where  $v_i$  is initial reaction velocity for the enzyme-catalyzed reaction in question,  $[S]$  is substrate concentration, and  $K_m$ , the Michaelis constant, is the *dissociation constant* for the enzyme-substrate complex: i.e., the equilibrium constant for the reaction  $ES \rightleftharpoons E + S$ . In this simple case therefore,  $K_m = \frac{k_2}{k_1}$  where the small  $k$ 's are defined as above. In case the decomposition of the  $ES$  complex to yield enzyme + products is not strictly rate-limiting,  $K_m$  must be interpreted<sup>3</sup> as  $\frac{k_2 + k_3}{k_1}$ . It will be noted that in the simplest case  $K_m$  is an inverse measure of the affinity of enzyme for substrate: i.e. the smaller the  $K_m$  value, the higher the affinity.

In theory,  $K_m$  is equal to the substrate concentration when  $v_i = \frac{1}{2}V_m$ . However, in determining  $K_m$  values, Equations (5) and (5a) are not very suitable, since  $V_m$  is not easily obtained. Equation (5) is a branch of an hyperbola, but in practice if an attempt is made to obtain  $V_m$  from an estimate of the horizontal asymptote, large errors usually occur for various reasons. However, it is possible, as shown by Lineweaver and Burk,<sup>4</sup> to transform Equation (5) into a linear equation simply by equating the reciprocal of both sides and simplifying by division. Equation (6) is thus obtained:

$$(6) \quad \frac{1}{v_i} = \frac{1}{V_m} + \frac{K_m}{V_m[S]}$$

Here the intercept is  $\frac{1}{V_m}$  and the slope is  $\frac{K_m}{V_m}$ . There is one objection to this transformation, however; namely, that points representing very low substrate concentrations, which are likely to be inaccurate, are given too great weight, since they become increasingly spread out in the plot of  $\frac{1}{v_i}$  against  $\frac{1}{[S]}$ . A second type of transformation of the original Equation (5) is better in this respect. It is obtained by multiplying the last equation, (6), by  $[S]$  to give:

$$(6a) \quad \frac{[S]}{v_i} = \frac{[S]}{V_m} + \frac{K_m}{V_m}$$

If  $\frac{[S]}{v_i}$  is plotted against  $[S]$ , the slope is  $\frac{1}{V_m}$ , and the intercept is  $\frac{K_m}{V_m}$ . From the intercept and the slope,  $K_m$  is therefore readily obtained.

<sup>3</sup> Briggs and Haldane: *Biochem. J.*, **19**, 338 (1925); Wilson: Chapter in Lardy (ed.): *Respiratory Enzymes*, Minneapolis, Burgess Publishing Co., 1950, p. 17.

<sup>4</sup> Lineweaver and Burk: *J. Am. Chem. Soc.*, **56**, 658 (1934); *Respiratory Enzymes*, loc. cit.

The affinity of enzyme for substrate is of the utmost importance and may eventually turn out to be the determining factor in deciding why an enzyme consisting of a protein plus a prosthetic group is so much more efficient as a catalyst than the prosthetic group alone.

**Synthetic Action of Enzymes.** Enzymic reactions can be divided into two classes:

- (1) Exergonic, or those which liberate energy.
- (2) Endergonic, or those which require addition of energy in order to occur.

The reactions which result in the synthesis of glucose-1-phosphate from glucose, glutamine from glutamic acid and ammonia, acetylcholine, urea, peptides, riboflavin phosphate, coenzyme I, etc., are endergonic. The energy for these reactions is supplied by the breakdown of adenosine triphosphate.

Enzymic reactions can be divided also into:

- (a) Those which proceed to completion.
- (b) Those which proceed to a point of equilibrium at which both substrate and products are present in measurable amounts.

Examples of (a) are the decomposition of hydrogen peroxide by catalase, the formation of rhodanate from cyanide and thiosulfate by rhodanese and the synthesis of gum dextran from sucrose by dextran sucrase. An example of (b) is the conversion of glucose-6-phosphate to glucose-1-phosphate by phosphoglucomutase. At equilibrium the digest will contain 5 per cent of glucose-1-phosphate and 95 per cent of glucose-6-phosphate.

One of the most striking demonstrations of the reversibility of enzyme action can be obtained with phosphorylase. This enzyme, which is found in animal tissues as well as tissues of plants, catalyzes the breakdown of glycogen or starch to glucose-1-phosphate:

The glucose-1-phosphate (Cori ester) can be isolated readily from the system. If glucose-1-phosphate is added to a potato phosphorylase preparation, starch amylose is rapidly formed and can be detected by the color it gives with iodine solution. For this reaction to occur it is necessary to prime the digest by adding a trace of glycogen or starch. Muscle phosphorylase likewise produces starch from glucose-1-phosphate. Phosphorylases prepared from liver, brain, heart, or yeast form glycogen from glucose-1-phosphate. These phosphorylases contain two enzymes, ordinary phosphorylase, which forms 1-4 linkages, and the Q enzyme, which forms 1-6 linkages. The latter is not a true phosphorylase, but a transglucosidase.

The possibility of reversible or synthetic action of enzymes has thus been demonstrated, and it is of the greatest interest to know the part that such reversible enzyme action may play in the synthesis of proteins, fats, carbohydrates, and other substances in the animal body.

## OXIDATION AND REDUCTION SYSTEMS

Most if not all of the energy of living matter is derived from oxidative processes. Oxidation involves the loss of negative electrons from the sub-

stance oxidized, these electrons passing to the oxidizing agent which is simultaneously reduced. Thus the reaction of ferric chloride with potassium iodide involves a transfer of electrons from the iodide ions to the ferric ions so that the iodide is said to be oxidized and the iron reduced. Biological oxidations involve the same transfer of electrons.

In many oxidations the products of the reaction possess less energy than the reacting substances, and in these cases energy is liberated as heat or in some other form.

Many oxidations are coupled with the formation of esters of phosphoric acid such as adenosinetriphosphate. Inorganic phosphate is used to form these esters. The esters which are formed primarily are very labile, and there is a considerable free-energy decrease (about 10,000 calories) when they are hydrolyzed. Such an ester is adenosinetriphosphate, which contains two such labile phosphoric acid groups. These labile phosphoric acid residues are connected in a manner similar to that found in pyrophosphoric acid and the bond is sometimes called a high-energy phosphate bond. The formation of such compounds is a matter of considerable significance. It suggests how a cell might make use of the energy of oxidation. For example, in the presence of hexokinase from yeast or muscle, the following reaction occurs:

Thus glucose is changed into a form in which it can readily enter into the intermediate reactions of carbohydrate metabolism. One might ask why phosphatase could not do the same thing with glucose. Phosphatase catalyzes the following reaction:

It is commonly considered that all enzyme reactions are reversible. However, thermodynamic considerations suggest that, although this reaction may be reversible, the equilibrium would be so far to the right that the reverse reaction would be physiologically insignificant. Thus there would be very little glucose-6-phosphate formed. On the other hand, in the reaction cited with adenosinetriphosphate, the equilibrium position is far to the side of glucose-6-phosphate and adenosinediphosphate. In this way it is thought that the cell can use at least part of the energy produced by oxidation reactions to form materials which are useful to the cell.

**Oxidation of Hydrogen.** The first steps in the oxidation of fats, carbohydrates and proteins are dehydrogenations, brought about by enzymes known as dehydrogenases. About 40 dehydrogenases are known. In many instances the fats, carbohydrates, and proteins are not dehydrogenated as such, but are first broken down by hydrolysis or desmolysis to simpler compounds, i.e. diphosphoglyceric aldehyde, glycerophosphate, choline, amino acids, etc.

The individual dehydrogenases are frequently composed of a specific protein loosely united with coenzyme I or coenzyme II. Coenzyme I is

also known as diphosphopyridine nucleotide, or DPN. Coenzyme II is triphosphopyridine nucleotide, or TPN.

The hydrogen that is split off unites with these coenzymes, forming DPNH and TPNH. The hydrogen may be next taken up by TPN-cytochrome C reductase, or by DPN-cytochrome C reductase:

This enzyme next reacts with cytochrome C:

Finally, in the presence of atmospheric oxygen and cytochrome oxidase, the oxidation is completed:

Some of the hydrogen present in substrates enters the Krebs cycle and is split off at one stage or another. One of these reactions involves succinic acid, which is oxidized by the succinic oxidase system. Here the initial reaction is:

The route traveled by the hydrogen is probably as follows:

If some easily reduced dye, such as methylene blue, is present it will be reduced to leucomethylene blue in the presence of succinic acid:

When leucomethylene blue comes in contact with oxygen it is reoxidized, forming methylene blue and hydrogen peroxide:

A number of yellow enzymes (old yellow enzyme, xanthine oxidase, glucose oxidase of molds, D-amino acid oxidase) in the reduced state can react with gaseous oxygen to form hydrogen peroxide. In living cells this hydrogen peroxide is very rapidly decomposed by the enzyme catalase. This reaction is:

Catalase is a heme-protein found in all living cells, with the exception of certain bacteria. Its function appears to be the removal of the hydrogen peroxide, which is toxic. Keilin and Hartree have observed that catalase can utilize hydrogen peroxide to oxidize methyl and ethyl alcohols to the corresponding aldehydes. On account of this reaction Theorell has sug-

gested that catalase is an important peroxidizing enzyme. However, this hypothesis has little to support it at the present time.

The hydrogen peroxide may also be removed by peroxidase. This enzyme, in the presence of  $\text{H}_2\text{O}_2$ , oxidizes various phenolic compounds and amines, such as pyrogallol, guaiacol, hydroquinone, tyrosine, adrenaline, etc. Peroxidase is a heme-protein; in fact, even hemin itself has a very slight peroxidase action. Peroxidase, like other heme-containing enzymes, is inhibited by  $\text{HCN}$ ,  $\text{H}_2\text{S}$ , and sodium azide.

Oxidation by activation and transfer of hydrogen also occurs in the oxidation of aldehydes. First of all, the aldehyde is hydrated:

The hydrated aldehyde is then oxidized:

This type of oxidation occurs in the oxidation of acetaldehyde to acetic acid by aldehyde dehydrogenase. Similarly alcohol dehydrogenase mediates the oxidation of alcohols to aldehydes; as, for example, vitamin A to retinene.

**Cytochromes.** By use of the spectroscope, Keilin was able to demonstrate in living cells the presence of three closely related substances which he called cytochromes A, B, and C. Cytochromes appear to be present in all living cells except a few bacteria. The cytochromes are heme-protein compounds. The absorption bands of the reduced cytochromes may be easily observed by looking at a yeast suspension with a spectroscope. If a stream of air is bubbled through the suspension, the cytochromes are oxidized and the bands disappear. In animal tissues the cytochromes commonly exist predominantly in the oxidized form.

**Oxidation by Activation of Oxygen.** Warburg found in living cells a heme-containing compound which has the property of activating oxygen and which he called the respiratory enzyme. The activity of the enzyme is dependent upon the iron present, since  $\text{HCN}$ , in small amounts, and carbon monoxide inhibit the action, apparently through combination with the metal. The inhibition by carbon monoxide can be obtained only in the dark. Warburg's respiratory enzyme is apparently identical with the enzyme formerly called indophenol oxidase and now known as cytochrome oxidase.

Cytochrome oxidase, in the presence of molecular oxygen, oxidizes reduced cytochrome C, as has already been described.

Cytochrome C is reduced by such substrates as hydroquinone and by the Nadi reagent, a mixture of dimethyl *p*-phenylenediamine and  $\alpha$ -naphthol. Here the reaction is:

**Yellow Enzymes.** TPN-cytochrome C reductase and DPN-cytochrome C reductase are yellow enzymes. These enzymes contain riboflavin (vitamin B<sub>2</sub> or G) in their prosthetic groups. The prosthetic group of cytochrome C reductase consists of riboflavin phosphate (isoalloxazine-D-ribose-phosphate) which is sometimes called a mononucleotide. There are other yellow enzymes which contain such mononucleotides as prosthetic groups. An example is the old yellow enzyme of Warburg. Other yellow enzymes contain prosthetic groups composed of riboflavin-phosphate-phosphate-D-ribose-adenine. Such a compound is called a dinucleotide. Examples of yellow enzymes which contain isoalloxazine-adenine dinucleotide prosthetic groups are diaphorase, the Haas yellow enzyme, xanthine oxidase, and D-amino acid oxidase. These yellow enzymes function in hydrogen transport as outlined above. It is the prosthetic group of these enzymes which is oxidized and reduced.

**Copper Enzymes.** There are various enzymes which contain copper. These are all inhibited by HCN in much the same way as the iron-containing enzymes cytochrome oxidase, catalase, and peroxidase. One of these copper enzymes is tyrosinase. This enzyme is apparently identical with monophenoloxidase and polyphenoloxidase. This enzyme oxidizes various phenolic compounds such as phenol, catechol, cresols, tyrosine, pyrogallol, and dopa (3,4-dihydroxyphenylalanine). For example:

Water, not hydrogen peroxide, is always formed as a result of oxidation by this enzyme, and gaseous oxygen is used as the hydrogen acceptor.

Tyrosinase is also inhibited by  $\text{H}_2\text{S}$  and by  $\text{CO}$ . The inhibition by carbon monoxide is not influenced by light. Tyrosinase is commonly found in plant tissues, bacteria, and fungi; it also occurs in animals. Tyrosinase is very similar to laccase, which is also a copper-containing enzyme. Laccase is found in various plant tissues and differs from tyrosinase in that it does not oxidize tyrosine or *p*-cresol.

Ascorbic acid oxidase is another plant copper-containing enzyme. It catalyzes the oxidation of L-ascorbic acid (vitamin C) in the presence of oxygen:

The dehydroascorbic acid may be reduced by hydrogen sulfide.

It has been proposed by various workers that one or more of these copper-containing enzymes function in plant tissues in much the same way as does cytochrome oxidase in animal tissues. The matter is as yet unsettled.

**Sulfhydryl Group in Oxidations.** Practically all tissues give a purple color with sodium nitroprusside and ammonia. This indicates the presence of the sulfhydryl group  $\text{R}-\text{SH}$ . Such a group is found in the amino acid cysteine  $\text{HOOC}\cdot\text{CH}(\text{NH}_2)\cdot\text{CH}_2\text{SH}$ . Cysteine is not, however, found to any extent in the tissues as such but is found in appreciable amounts in the form of glutathione, a tripeptide of glycine, cysteine, and glutamic acid, which has the following structure:

On oxidation cysteine may be converted into the disulfide form, or cystine:  $\text{R}-\text{SH} + \text{HS}-\text{R} + \text{O} \rightarrow \text{R}-\text{S}-\text{S}-\text{R} + \text{H}_2\text{O}$ ; and the cystine may be reduced to cysteine:  $\text{R}-\text{S}-\text{S}-\text{R} + 2\text{H} \rightarrow 2\text{R}-\text{SH}$ . Glutathione may also be oxidized to the disulfide form  $2\text{G}-\text{SH} \rightarrow \text{G}-\text{S}-\text{S}-\text{G}$ , this reaction also being reversible. The widespread occurrence of glutathione and the amounts found in cells indicate its importance, but its mode of action is not yet clear. Glutathione has been synthesized both by methods of organic chemistry and by the use of enzymes.

**New Coenzymes.** In recent years the list of coenzymes has increased considerably. Thus, we have uridine diphosphoglucose necessary for the

conversion of galactose-1-phosphate to glucose-1-phosphate by the enzyme known as phosphogalactose isomerase. Coenzyme III, found in yeast, is required for the oxidation of L-cysteine sulfinic acid to cysteic acid.

A yet more interesting coenzyme is *coenzyme A*, containing pantothenic acid (q.v., Chapter 35), adenylic acid, and mercaptoethanolamine. Coenzyme A functions in the acetylation of aromatic amines by pigeon liver homogenates in the presence of acetic acid and ATP. Here the intermediate product is acetyl coenzyme A. Coenzyme A is required for the acetylation of choline by nervous tissue. Aged extracts of autolyzed pigeon liver convert oxalacetic acid to citric acid if coenzyme A, ATP, magnesium ions and acetate are present. Coenzyme A is necessary for the catalytic transfer of acetyl-bound phosphate, as well as for the arsenolysis of acetyl phosphate by the phosphotransacetylase of *Clostridium kluyveri*. In this process coenzyme A accepts an acetyl group from pyruvic acid and forms acetyl phosphate. The enzyme present is phosphotransacetylase, which occurs neither in animals nor in yeast. Bacterial phosphotransacetylase together with an enzyme from pigeon liver can employ synthetic acetyl phosphate to synthesize acetoacetic acid.

Coenzyme A is thought to be involved in the synthesis of phospholipides. Here ATP supplies the energy. It was found that yeast extracts convert coenzyme A to a pyrophosphate in the presence of ATP. This compound can react with acetate to give rise to acetyl coenzyme A and pyrophosphate.

*6-Thioctic acid* (lipoic acid, or 6,8-dithio-n-octanoic acid) has been isolated in crystalline form from liver and from yeast. This substance is necessary for the growth of the protozoan *Tetrahymena gelii* and is able to replace acetate needed for the growth of *Lactobacillus casei*. It appears that lipoic acid is necessary for the oxidation and dismutation of pyruvic acid by *Streptococcus fecalis*, and that the formation of acetyl coenzyme A and succinyl coenzyme A requires the presence of both thiamine pyrophosphate and lipoic acid. Thioctic acid is discussed further in Chapter 35.

## EXPERIMENTS ON ENZYMES<sup>5</sup>

### ROLE OF IRON IN OXIDATIONS

**1. Catalytic Decomposition of Hydrogen Peroxide by Metals.** Transfer 5-ml. portions of hydrogen peroxide to each of 4 test tubes. To one add a very small amount of finely divided metallic platinum,<sup>6</sup> to the second a small amount of powdered magnetite ( $\text{Fe}_3\text{O}_4$ ), to the third a similar amount of ordinary ferric oxide or hematite ( $\text{Fe}_2\text{O}_3$ ), and to the fourth a small amount of magnetite and a few drops of 1 per cent NaCN (*Poison!*). Note any evolution of gas. After

<sup>5</sup> If it is deemed advisable by the instructor to give all the practical work upon enzymes at this point in the course, additional experiments will be found in the chapters on digestion.

<sup>6</sup> Use a solution of colloidal platinum (see p. 10) or a powder prepared by dipping filter paper in platinic chloride solution and igniting in a crucible. Welo and Baudisch have shown that magnetite produces active oxygen even when heated to 330° C., although it then has the same composition ( $\text{Fe}_2\text{O}_3$ ) as it has when heated still further to 550° C.; but the latter product sets free molecular, not active, oxygen. Ferrous hydroxide also catalyzes a rapid decomposition of peroxide.

a few minutes add a few drops of an alcoholic solution of guaiac. This is oxidized to a blue color by active oxygen. Which tubes show this reaction? Cyanide paralyzes cell respiration, apparently by inactivating the iron which is an essential part of the system.

## EXPERIMENTS ON PLANT OXIDASES

**1. Demonstration of Potato Oxidases.** It is convenient to combine the study of potato oxidases with a study of the composition of the potato. This throws light on the value of the potato as a food. It also gives information as to the composition of a typical vegetable cell.<sup>7</sup>

(a) **PREPARATION OF POTATO EXTRACTS.** Wash and peel a medium-sized potato. Grate rapidly and transfer the gratings at once to a piece of cheesecloth which is suspended in a beaker containing about 200 ml. of distilled water. Work gently with the hand to get out as much of the starch as possible. Keep this extract (water extract No. 1). Make a second extraction using 200 ml. of distilled water (water extract No. 2). Make a third extraction, and if this does not contain an appreciable amount of starch, discard it. Work the pulp until it is practically starch-free.

(b) **TESTS ON PULP.** Work a portion of the pulp very thoroughly with water until it is practically free from starch as indicated by the iodine test. Test for protein, using Millon's test, and for carbohydrate by the Molisch test.

(c) **TESTS ON WATER EXTRACT NO. 1.** Pour off the supernatant liquid from the extract when the starch has settled out. Filter. Test for reducing sugars by Benedict's test. Test for protein. Boil 20 ml. of the extract and filter. Test the filtrate for inorganic chlorides, sulfates, and phosphates. Indicate in your notebook what information you have obtained as to the food value of the potato.

(d) **SEPARATION OF STARCH.** Combine the starch obtained from extracts No. 1 and No. 2. Wash by decantation with distilled water. Drain off the water and turn the beaker upside down so that the starch will drain; otherwise molds may develop.

(e) **EXPERIMENTS ON POTATO OXIDASE.** Into each of a series of 5 clean test tubes introduce 5 ml. of potato extract (extract No. 2 filtered). (If the extract is kept over, it must be preserved with toluene.) Introduce other reagents according to the following series: (1) Potato extract + 10 drops of 1 per cent phenol,<sup>8</sup> (2) potato extract + 10 drops of 1 per cent catechol, (3) potato extract + 10 drops of guaiac solution, (4) potato extract + 10 drops of pyrogallol solution, and (5) potato extract + 5 drops of  $\alpha$ -naphthol solution + 5 drops of *p*-phenylenediamine hydrochloride solution. This combination of  $\alpha$ -naphthol and *p*-phenylenediamine is known as the Nadi reagent.

Mix the contents of the tubes by shaking. Watch for any color changes. If necessary let stand until the next laboratory period (add toluene), and examine again. In this experiment the phenol  $C_6H_5OH$ , catechol  $C_6H_4(OH)_2$ , and pyrogallol  $C_6H_3(OH)_3$  are oxidized with the production of brown-colored compounds. The guaiaconic acid in the guaiac is oxidized to guaiac blue. In the last tube we have the production of indophenol from the  $\alpha$ -naphthol and phenylenediamine under the influence of oxidase.

Two oxidases appear to be active in these tests. Monophenoloxidase (also called polyphenoloxidase and tyrosinase) is responsible for the

<sup>7</sup> This experiment is based upon the laboratory directions of Dr. William H. Welker.

<sup>8</sup> The phenol, catechol (pyrocatechol), *p*-phenylenediamine hydrochloride, and pyrogallol are 1 per cent aqueous solutions. The  $\alpha$ -naphthol is a 1 per cent solution in 95 per cent alcohol. For the guaiac solution dissolve 0.5 g. of gum guaiac in 30 ml. of 95 per cent alcohol.

oxidation of the phenol to catechol, then to *o*-quinone, and finally with condensation reactions to brown compounds of uncertain composition.

Polyphenoloxidase also acts upon catechol to form *o*-quinone and then the brown compounds just mentioned. It also acts upon pyrogallol forming purpurogallin.

Cytochrome oxidase in the presence of cytochrome C oxidizes the *p*-phenylenediamine and in the presence of  $\alpha$ -naphthol there is formed indophenol.

Peroxidase in the presence of hydrogen peroxide also gives this reaction. At least part of the color obtained in the above test is due to the action of peroxidase since the color develops more slowly if catalase is added to the potato oxidase preparation.

The oxidation of the guaiaconic acid of the guaiac to guaiac blue is apparently due to the action of the *o*-quinones formed as indicated above, on the guaiac, rather than any direct action of the enzymes on the guaiac itself except in the case of the slight peroxidase action due to the presence of some peroxide. Peroxidase appears to oxidize the guaiac directly.

**2. Experiments on Potato Peroxidase.** Prepare a series of 5 tubes containing 5-ml. portions of potato extract and 10 drops of oxidase reagents as in the preceding experiment. Prepare still another series, but use potato extract previously boiled for 5 minutes. Then to each tube add 10 drops of 3 per cent hydrogen peroxide solution. Note whether oxidation takes place more rapidly than in Exp. 3 where no hydrogen peroxide is used. Is the peroxidase destroyed by boiling?

The potato has a greater peroxidase than phenoloxidase activity, which accounts for the more rapid action in the presence of  $\text{H}_2\text{O}_2$ .

**3. Resistance of Oxidase and Peroxidase to Heat.** Into each of 3 test tubes intr duce 5 ml. of potato extract. Put in a water bath at  $70^\circ$  for 10 minutes. To the first tube add 2 drops of 1 per cent catechol solution and then to each 10 drops of guaiac solution, and to the third tube only, 10 drops of hydrogen peroxide solution. The appearance of a blue color in the presence but not in the absence of hydrogen peroxide indicates that peroxidase is not destroyed at  $70^\circ$  but that the phenol oxidase is not stable at this temperature. How would you prepare a solution containing peroxidase but not oxidase? The

fact that the addition of catechol does not suffice to bring back the direct oxidase action indicates that it is not the catechol compounds but the oxidase that is destroyed at this temperature.

**4. Role of Catechol Compounds in Oxidase System.** Into each of 2 clean test tubes introduce 5 ml. of potato extract. To one, add 1 drop of 1 per cent catechol solution. Let stand for 5 minutes. Then to each tube add 10 drops of guaiac solution. Let stand and note any color change.

Most potatoes contain relatively little of the catechol compounds. The addition of catechol therefore hastens the oxidation of the guaiac, since the oxidation of the guaiac is secondary to the formation of *o*-quinones from catechol compounds, the *o*-quinones being capable of directly oxidizing guaiac.

**5. Preparation of Peroxidase.** Scrapings of horseradish may be extracted with alcohol and dried. On extraction with water these dried scrapings give a peroxidase solution free from oxidase. By a more complicated process a preparation showing about 1,000 times the activity of the original material has been obtained.

**6. Determination of Peroxidase.** Into a 250-ml. flask introduce 100 ml. of a saturated solution of leucomalachite green,<sup>9</sup> 2 ml. of 0.166 N sodium acetate saturated with toluene, 1 ml. of hydrogen peroxide,<sup>10</sup> and from 0.0025 to 0.05 unit of peroxidase in not more than 5 ml. of solution. All should be brought to 20° C. before mixing and kept at that temperature. Measure 10 ml. of N H<sub>2</sub>SO<sub>4</sub> into a small flask, and add all at once at the end of 5 minutes to the digestion mixture to stop the action. Rinse the small flask with 5 ml. of water. After 15 to 30 seconds, neutralize with a little more than an equivalent amount of NaOH solution. Shake vigorously to eliminate bubbles of CO<sub>2</sub>. Compare with a standard malachite green solution containing 10 mg. per liter, and set at 5 or 10 mm. The standard is made up in 0.05 N acetic acid and preserved with toluene. Yellow artificial light is better than daylight for the comparison. Under the given conditions one unit of peroxidase forms 53 mg. of malachite green.

**7. Demonstration of Catalase.** Mix about 1 g. ground liver with 3 ml. water and add a few ml. 3 per cent hydrogen peroxide. Test the gas evolved for oxygen, using a glowing match.

## EXPERIMENTS ON ANIMAL OXIDASES

**1. Schardinger Reaction.** Place 5 ml. of milk in each of 3 test tubes. Heat one to boiling and cool. To each tube add 1 ml. of 0.02 per cent methylene blue solution. To tubes 1 and 2 add 1 ml. of 0.4 per cent formaldehyde solution. Mix by gentle rotation, add 1 to 2 ml. of paraffin oil, and put in a water bath at about 40° C. The milk in tube 2 should gradually decolorize. The

<sup>9</sup> The dye should be recrystallized twice from alcohol, once from petroleum ether, and again from alcohol. Saturate titrated 0.05 N acetic acid with the dye at 20° C. The solution freed from air under a vacuum will keep for months. If precipitation occurs, warm to redissolve.

<sup>10</sup> Dilute 30 per cent hydrogen peroxide (reagent grade) 100 times. Titrate an aliquot with KMnO<sub>4</sub> after adding sulfuric acid and dilute further so that each ml. contains 0.25 mg. H<sub>2</sub>O<sub>2</sub>.

reaction is an example of anaerobic oxidation in the presence of a hydrogen acceptor (methylene blue) and may be written thus:

This reaction is given more slowly by milk which has been heated and more rapidly by milk which has a high bacterial count.

**2. Study of Tissue Oxidations by the Methylene Blue Method of Thunberg and Ahlgren: Principle.** Finely divided tissue is suspended in a solution containing methylene blue, phosphate solution to regulate the acidity, and the substance whose action it is desired to determine. The tube is evacuated, placed in a water bath, and the time required for the methylene blue to be decolorized is determined. This is a measure of the rate of oxidation in the mixture. The nature of the substances capable of being oxidized by the tissue can be determined and the influences governing the oxidation process studied.

**Procedure.** The tube<sup>11</sup> most convenient for use in this experiment is illustrated in Fig. 77. Into each of 3 tubes introduce 0.9 ml. of a mixture of 8 ml. of methylene blue 1:2000 and 6 ml. of a phosphate buffer of pH 7. Then add 0.1 ml. of water to the first tube, of 0.1 M potassium succinate to the second, and of 0.1 M potassium glycerophosphate to the third. Then add 0.2 g. of finely divided washed rabbit muscle<sup>12</sup> to each. Evacuate each tube for 2 or 3 minutes with a strong water-jet filter pump.<sup>13</sup> Place the tubes in a constant-temperature water bath at 35° C. Observe from time to time and note when each tube just loses its last trace of blue color. Record the number of minutes required in each case. Do the succinate and glycerophosphate solutions decolorize first? What does this indicate as to the oxidation of these substances by muscle tissue?

FIG. 77. VACUUM TUBE. (THUNBERG.)

**3. Nitroprusside Reaction for Glutathione.** Rub up in a mortar a small piece of fresh liver or kidney tissue, a little sand, and a few ml. of saturated

<sup>11</sup> The tube is made of hard, colorless glass and is of about 10 ml. capacity. The stopper is greased with a mixture of: rubber 1 part, petroleum jelly 2 parts, and heavy liquid petroleum 1 part. Tubes may be obtained from the Scientific Glass Apparatus Co., Fisher Scientific Co., and others.

Solutions required are: Stock solution of methylene blue, 1 g. in 500 ml. of water. Phosphate buffer solution of pH 7.

<sup>12</sup> The muscles of frogs and other animals may also be used. The animals should be killed by a blow and not by anesthesia. One or more g. of muscle tissue freed as much as possible from ligaments, fat, and blood are cut up on a watch glass with a scissors of the Cooper type for 3 to 5 minutes. A drop or two of water may be added to assist cutting. The tissue may then be washed if desired by shaking with an excess of water, rubbing in a mortar, straining through silk, and drying with filter paper. Keep in a covered beaker placed in a dish containing pieces of ice. The divided tissue is best used as soon as possible but may generally be kept for an hour at 20° C. Uncut tissue may be kept somewhat longer. In weighing the tissue a microbalance weighing up to 500 mg. is convenient, a small celluloid shell being attached to hold the material. A glass rod with a spoon-shaped tip is used to introduce the tissue into the tube.

<sup>13</sup> There may be some foaming during the evacuation, which should be continued until the solution boils when warmed with the hand. Foaming may be reduced by rotating the tube in a horizontal position so as to distribute the material on the sides of the tube or by first putting the tubes in cold water. After evacuation, to get all material into the bottom of the tubes they may be rotated for a few seconds in a hand centrifuge. It is also well after evacuation and closing the stopper to remove the tube from the side tube while holding both under water. The side tube is filled with water so that leakage of air is less probable.

ammonium sulfate solution. Add 5 or 6 drops of 2 per cent sodium nitroprusside and 2 ml. of concentrated ammonium hydroxide solution. The mixture turns purple.

4. *Estimation of Glutathione in Tissue.* See Chapter 23.

5. *Preparation of Glutathione:*<sup>14</sup> *Procedure.* Add 20 ml. of concentrated  $\text{H}_2\text{SO}_4$  slowly to 100 ml. of 89 per cent alcohol, keeping the mixture cool. When cold add 80 ml. of ether. Pour on to 2,000 g. of compressed bakers' yeast, coarsely crumbled in a large jar. Stir for a few minutes until homogeneous. Pour on to 2 large Buchner funnels, the papers being covered with

FIG. 78. CRYSTALS OF GLUTATHIONE.

(Left) First crystallization. (Right) Recrystallized.

Courtesy, Kendall, McKenzie, and Mason: *J. Biol. Chem.*, 84, 657 (1929).

thin layers of kieselguhr. After 4 hours, filtration may nearly stop. If so, pour off the fluid upper layer on to another filter, and suck dry for a few hours more. Do not use too high a vacuum at first or the mixture will froth as the ether boils off.

The combined filtrates (about 1100 ml.) are titrated with NaOH, using Congo red as an indicator (the filtrate is generally just acid to Congo red), and the amount of 20 per cent  $\text{H}_2\text{SO}_4$  necessary to bring the filtrate to 0.5 N added.

Prepare about 1 g. of cuprous oxide by boiling ordinary Fehling's solution with an excess of glucose cautiously added. It should be bright red. Wash by decantation on a filter. It may be kept in a dry state. Rub up and suspend in about 30 ml. of water. With thorough stirring add 2-ml. portions of suspension at a time to the yeast extract previously carefully warmed on a water bath with stirring to 50° C. When about half of the oxide has been added, allow the salt to settle, and pour the mother liquor off for further additions of oxide. At a later stage the addition of cuprous oxide will cause the re-solution of some of the cuprous-glutathione compound already formed. When this occurs, reprecipitate by blowing air through the solution for about an hour. The precipitate redissolves on very prolonged aeration. Although

<sup>14</sup> For a procedure involving the use of a supercentrifuge see Kendall, Mason, and McKenzie: *J. Biol. Chem.*, 87, 55 (1930); 88, 409 (1930).

flocculent and amorphous, this compound has the normal copper content (17 per cent) and gives crystalline glutathione on decomposition.

Wash the cuprous salt with 0.5 N  $\text{H}_2\text{SO}_4$  on the centrifuge and then with water until the washings are free from sulfate. If a centrifuge is used, about 10 washings are required. Or use a device prepared with two Jena sintered glass filters (grade 4) of suitable size. Put the cuprous salt in one and place the other upside down on top, a water-tight joint being made with a piece of wide rubber tubing. Connect the lower funnel to a reservoir of distilled water about a meter above it, and attach the upper one to a flask and filter pump. Wash until the filtrate remains free from sulfate after shaking the filtration apparatus.

Suspend the precipitate in four to five times its bulk of distilled water, and decompose with well-washed  $\text{H}_2\text{S}$ . Filter. Free from  $\text{H}_2\text{S}$  by a stream of hydrogen. Evaporate to a small bulk in a vacuum desiccator at room temperature. If the volume of filtrate is too large for this and distillation in vacuum is necessary, use a good pump and distil at  $25^\circ\text{C}$ . If the mixture does not crystallize spontaneously before reaching a sirupy consistency, rub with a glass rod to start crystallization. Yield, about 1.5 g. For the crystalline form of glutathione, see Fig. 78.

## PREPARATION AND PURIFICATION OF ENZYMES<sup>15</sup>

Purified enzyme preparations may be made from digestive secretions containing the enzyme. More often, however, the source is an animal or plant tissue. To obtain the enzyme in concentrated form it must be freed as far as possible from the mixture of substances making up the cell.

In the case of animal tissues the material should be immediately refrigerated and used as soon as possible. It may be cut up with a scissors or run through a meat-chopper and then rubbed in a mortar with quartz sand or ground glass. Freezing with liquid air or carbon dioxide will often aid comminution and check fermentative processes. The material may also in some cases be dehydrated by drying in a current of warm air or by dehydrating with acetone or alcohol followed by treatment with ether to remove fat, and then grinding very fine in a ball mill.

The comminuted tissue may then be extracted by use of a suitable solvent (e.g., water, salt solutions, glycerol, or solutions of definite pH) which will extract the enzyme with as little other material as possible. The mixture may then be filtered or centrifuged. Since enzymes are proteins, the greatest difficulties in enzyme purification are connected with the removal of protein contaminations. Methods used in the purification of proteins are therefore useful (see Chapter 6).

Just as with proteins, the exact procedure will vary in each case. The procedures generally required include dialysis, precipitation by means of salts or by liquids such as alcohol or acetone, and selective adsorption and elution. Dialysis, employing most commonly the collodion bag, removes soluble diffusible substances including the salts that may be used in precipitation. Electrodialysis may also be employed. By means of fractional precipitation with salts such as ammonium sulfate, separation from many protein materials may be accomplished. In some cases alcohol may inactivate the

<sup>15</sup> This subject has been reviewed by Schwimmer and Pardee: *Advances in Enzymol.*, 14, 375 (1953).

enzyme. Among the most useful adsorbents are different types of aluminum hydroxide. For example, by choosing a suitable form of this adsorbent and the proper acidity of solution, separation of the enzymes of the pancreas has been accomplished. Associated with adsorption methods is of course the elution of the adsorbed material from the aluminum hydroxide-enzyme complex by suitable solvents, among which are solutions of alkali phosphates of different reactions or dilute ammonia. For the preparation of the different forms of aluminum hydroxide see footnote 16. Since preparations of pure

<sup>16</sup> *Preparation of Adsorbents: Alumina A.* Warm 250 g. of  $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$  in 750 ml. of water to 55° C. and pour the solution all at once with the most vigorous mechanical stirring into 2.5 liters of 15 per cent ammonia warmed to 55°. The temperature rises to 58° and is kept between 55° and 60° C. with continued stirring for half an hour. Transfer to a 5-liter flask with a reflux condenser and boil gently for 48 hours. Dilute in a jar with water to 12 liters. Wash 3 times by decantation. Stir the precipitate with 500 ml. of 15 per cent ammonia to decompose the traces of basic sulfate. Wash until for three successive times the wash water no longer comes away clear, and the precipitate becomes a plastic gel from which the wash water can be completely poured.

*Alumina B.* Precipitate as for *Alumina A*. After the precipitation stir for not more than half an hour. Then dilute at once to 12 liters and wash by decantation as above.

*Alumina Ca.* Ammonia alum is used. Ammonia used should be standardized by titration and should be measured accurately. Dissolve 22 g. ammonium sulfate in 600 ml. of water. Warm to 63° C. and add 100 ml. of 10 per cent ammonia. Warm quickly to 58°. Add with vigorous mechanical stirring all at once a solution of 76.7 g. of ammonia alum in 150 ml. of water, this solution being previously warmed to 58°. The temperature rises to 61°. Do not let the temperature go below 58° C. Ten minutes after beginning precipitation, separate as rapidly as possible from the mother liquor by centrifuging. Transfer with 1500 ml. of water containing 1.25 g. of  $\text{NH}_3$  to a 1500-ml. flask and shake. Centrifuge. Repeat using 2.5 g. of  $\text{NH}_3$ . Each treatment with ammonia requires about 17 minutes. Then wash three times more, using water only. The last supernatant fluid should remain turbid. The whole procedure from the first precipitation should require about  $2\frac{1}{4}$  hours, and must be expedited as the preparation is unstable.

*Alumina C $\beta$ .* The  $\alpha$  compound changes into the  $\beta$  form on standing a few hours. The flocculent suspension becomes a plastic gel less soluble in acid. The  $\beta$  form changes gradually (10 days to several months) into the  $\gamma$  form.

*Alumina C $\gamma$ .* Precipitate as for the  $\alpha$  form. Stir for 15 minutes at 60°. Transfer with 5 liters or more of water to a tall jar and wash by decantation. To the fourth wash water add 80 ml. of 20 per cent  $\text{NH}_3$  to decompose the basic sulfate. Wash 12 to 20 times more with water or twice after the supernatant fluid no longer becomes clear. Some months' standing under water is required for complete conversion to the  $\gamma$  form to take place. The precipitate becomes more flocculent and is insoluble in cold dilute or fairly strong  $\text{HCl}$ .

*Alumina D.* Dissolve 130 g. of pure commercial aluminum hydroxide with 140 g. of  $\text{KOH}$  (80 per cent) in 900 ml. of hot water. Dilute to one liter and filter. Dilute to 10 liters. Precipitate by running a gentle stream of carbon dioxide through the solution for two days. Decant and wash 12 times with water containing carbon dioxide and then with distilled water. The final washings remain turbid.

*Aluminum Metahydroxide.* If one of the above forms of aluminum hydroxide be heated suddenly with ammonia in a sealed tube to 250° C. and kept at that temperature for 8 to 9 hours, there is a complete conversion to the metahydroxide form.

*Kaolin.* Kaolin is best treated with acid before use. To 500 g. of kaolin add 1500 ml. of pure  $\text{HCl}$  (sp. gr. 1.18) and warm very slowly so that the mixture begins to boil at the end of the first day and then boil for another day. Wash with water by decantation. Repeat the treatment with acid and washing three times more. Wash with cold water until the washings show practically no acidity but the kaolin itself reacts strongly acid on litmus paper.

*Other Adsorbents.* Ferric hydroxide, magnesium oxide, and stannic and silicic acids are used. Substrates may also be used as specific adsorbents as tristearin for lipase, casein for trypsin, and coagulated egg albumin for pepsin.

*Elution.* Solutions of ammonia or of disodium phosphate are most generally useful in freeing adsorbed enzymes from combinations with alumina.

Different enzymes are differently adsorbed. The properties of an enzyme as far as adsorption is concerned may change during purification. In a general way the more finely dispersed gels such as alumina *A*, *B*, and *C* have more adsorptive power than those with less surface such as the microcrystalline *D* and metahydroxide. For numerous applications see Willstätter, *et al.*: *Untersuchungen über Enzyme*, Berlin, Julius Springer, 1928. Also Grassmann: *Ergebnisse Physiol.*, 27, 407 (1928); Oppenheimer: *Die Fermente und Ihre Wirkungen*, Leipzig, Thieme, Vol. 3, 5th ed., 1929.

crystalline enzymes are of the greatest interest, there follows a description of methods used in the preparation of certain of these. Methods for the preparation of active preparations of vegetable lipase and sucrase are also included since these are more readily obtained from vegetable sources. Other enzyme preparations are discussed in the chapters dealing with digestion.

**1. Preparation of Crystalline Urease.**<sup>17</sup> Dilute 158 ml. of redistilled acetone<sup>18</sup> to 500 ml. at 22° C. (= 31.6 per cent acetone). Pour over 100 g. of Arlco jack bean meal in a beaker. Stir 3 to 4 minutes and filter through a Schleicher and Schüll, No. 595, or Whatman, No. 1, filter. Allow about 150 ml. to filter at room temperature. Complete the filtration in the ice chest at 2° to 2.5° C., over night. Centrifuge off the crystals that form, using cold centrifuge tubes. Examine microscopically (see Fig. 75, p. 308). Drain and stir up with 5 to 10 ml. of cold 31.6 per cent acetone. Centrifuge again. Dissolve the crystals in 15 to 40 ml. of distilled water at room temperature, and free the solution from insoluble matter by centrifuging. The activity of the concentrated solution is not lost very rapidly provided the material is kept in the ice chest.

**2. Preparation of Crystalline Pepsin.** Dissolve 500 g. of Parke Davis pepsin (U.S.P. 1:10,000) in 500 ml. of water and add 500 ml. of N H<sub>2</sub>SO<sub>4</sub>. Add with stirring 1000 ml. of saturated MgSO<sub>4</sub> solution. Filter through fluted paper (S. and S. No. 1450½) and then with suction. Discard the filtrate. The precipitate must not stand at room temperature more than 24 hours.

PRECIPITATE 1. Wash twice with an equal volume of ⅔ saturated MgSO<sub>4</sub>. Filter with suction. Discard the filtrate.

PRECIPITATE 2. Stir with water to a thick paste and run in M/2 NaOH until complete solution. Great care must be taken to avoid local excess of NaOH. The pH must never rise above 5.0. Add M/2 H<sub>2</sub>SO<sub>4</sub> with stirring until a heavy precipitate forms (pH about 3.0). Let stand 3 to 6 hours at 8° C. Filter with suction.

PRECIPITATE 3. Stir with water to a thick paste at 45° C. Add M/2 NaOH carefully until the precipitate dissolves (filter if cloudy and discard the precipitate). Place the beaker containing the precipitate in a vessel containing about 4 liters of water at 45° C., inoculate with pepsin crystals, and allow to cool slowly. Cooling should require 3 to 4 hours and a heavy crystalline precipitate should form at about 30° to 35° C. (see Fig. 76, p. 308). Keep the solution at 20° C. for 24 hours. Filter off the thick crystalline paste with suction.

PRECIPITATE 4. Wash with a small amount of cold water and then with ½ saturated MgSO<sub>4</sub> and keep under saturated MgSO<sub>4</sub> at 5° C. The filtrate may be treated with M/2 H<sub>2</sub>SO<sub>4</sub> to attain a pH of 3.0, the amorphous precipitate filtered off and treated like Precipitate 3.

**3. Preparation of Crystalline Trypsin and Chymotrypsin.** Remove the pancreas from cattle within one hour after slaughter, and immerse in cold N/4 H<sub>2</sub>SO<sub>4</sub>. Drain off the acid, mince, and suspend for 24 hours in 2 volumes of N/4 H<sub>2</sub>SO<sub>4</sub> at 5° C. Strain through gauze. Add solid (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> to 0.4 saturation. Filter. Saturate to 0.7 saturation. Let stand 2 days at 5° C. Dissolve in water and re-fractionate between 0.4 and 0.7 saturation. Dissolve the precipitate from 0.7 saturation in 0.25 saturated (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>. Adjust to pH 5.0.

<sup>17</sup> Sumner: *J. Biol. Chem.* 69, 435 (1926); 70, 97 (1926). Sumner and Hand: *J. Biol. Chem.*, 76, 149 (1928). For the recrystallization of urease see Dounce: *J. Biol. Chem.*, 140, 307 (1941).

<sup>18</sup> Commercial acetone distilled over fused CaCl<sub>2</sub> and soda lime, to remove the water and acid.

Let stand 2 days at 25° C. Filter. Crystals are chymotrypsinogen. (Retain filtrate for trypsin.) Recrystallize chymotrypsinogen in 0.25 saturated  $(\text{NH}_4)_2\text{SO}_4$  at pH 5 about 8 times. Dissolve in N/50  $\text{H}_2\text{SO}_4$ . Adjust to pH 7.6. Add a trace of trypsin. Let stand 2 days at 5° C. Adjust to pH 4. Salt out in 0.7 saturated  $(\text{NH}_4)_2\text{SO}_4$ . Filter. Dissolve in N/100  $\text{H}_2\text{SO}_4$ . Let stand 24 hours at 25° C. Filter off chymotrypsin crystals.

Take the filtrate from the chymotrypsinogen crystallization for the preparation of trypsin. Adjust to pH 4.0, precipitate in 0.7 saturated  $(\text{NH}_4)_2\text{SO}_4$ , and refractionate between 0.4 and 0.7 saturated  $(\text{NH}_4)_2\text{SO}_4$ . Filter. Wash the precipitate from 0.7 saturation with sat.  $\text{MgSO}_4$ . Dissolve in 0.4 M borate of pH 9.0. Cool to 5° C. Bring to 0.5 saturation with  $\text{MgSO}_4$ . Let stand 3 days at 5° C. Filter off the crystals of trypsinogen. Wash with 0.5 sat.  $\text{MgSO}_4$ . Dissolve in N/50  $\text{H}_2\text{SO}_4$ . Bring to 0.5 sat. with  $\text{MgSO}_4$ . Add 0.4 M borate to give a pH of 9.0. Let stand 1 day at 5° C. and filter off the crystals of trypsin. Yield, about 6 g. from 7 liters of acid extract of the pancreas.

**4. Preparation of Vegetable Lipase: Procedure of Willstätter and Waldschmidt-Leitz.** Rub in a mortar to a paste 20 g. hulled castor beans.<sup>19</sup> Then with continued rubbing add 140 ml. of water in portions of 5 to 10 ml. Centrifuge for 15 minutes at 3,000 revolutions per minute. Three layers are formed. Pour off the upper creamy layer and retain. Pour off the clear water layer and discard. Rub up the residue with 140 ml. of water as before and centrifuge. Pour off the creamy top layer and combine with the first portion. Use this suspension for lipase experiments.

**5. Preparation of Sucrase from Yeast.** Introduce 100 g. of compressed yeast into a 400-ml. beaker. Warm the yeast to 30° C. by placing the beaker for some time in a water bath at a slightly higher temperature. Add 10 ml. of toluol. Stir thoroughly with a heavy glass rod. The yeast should become liquefied in 30 to 45 minutes. Add 200 ml. of water. Mix thoroughly and centrifuge. To the residue in the centrifuge tubes, add a small amount of water and mix well, then add more water at 30° C. to make a total of 200 ml. Stir and centrifuge. To the yeast residue after pouring off the water, add 100 ml. of water saturated with toluol and 10 ml. of toluol, and incubate at 30° C. over night. Dilute with 4 volumes of water. With vigorous stirring, carefully add acetic acid (not over 1 N) until a test with methyl red indicates a pH of about 3.5 to 4.0. Centrifuge. To the supernatant fluid add some infusorial earth and filter. Neutralize with ammonia to complete change of color with bromocresol purple. Keep in a refrigerator.

**6. Preparation of Crystalline Catalase.**<sup>20</sup> Put fresh beef liver through a meat grinder four times. Extract the catalase at room temperature by the occasional shaking of each kilogram of ground liver for 10 min. with 1 l. of distilled water. To each liter of material add 480 ml. of chilled solution of chloroform, 1 part; and ethyl alcohol, 2 parts. Shake violently for about 30 sec. and at once filter in the ice chest through Whatman No. 12 filter papers. The next day the filtrates will contain a sediment of catalase crystals. This sediment is centrifuged down in a refrigerated centrifuge and the supernatant liquid is discarded. The crystals are dissolved at room temperature in distilled water (30–40 ml. for each kilogram of liver used). The solution is

<sup>19</sup> The greatest care must be taken to avoid poisoning by the ricin which is present in the meats.

<sup>20</sup> Mosimann; *Arch. Biochem. Biophys.*, 33, 488 (1951).

centrifuged to remove a white amorphous impurity, decanted, and chilled in the ice chest for 12 to 24 hr. Catalase will precipitate as needles.

### QUANTITATIVE ESTIMATION OF ENZYME ACTION

The amount of enzyme present in any mixture is expressed in terms of its activity as compared with an arbitrary standard. Either the time required for a given amount of enzyme preparation to bring about a definite degree of conversion of the substrate or the amount of preparation needed to bring about a definite degree of conversion in a specified time may be made the basis of comparison. Inasmuch as enzyme action is greatly influenced by the pH of the solution, by the presence of inorganic salts and activators, and by temperature, it is important that the conditions in the digestion mixtures should be made as nearly identical as possible and that the enzyme if in inactive form should be properly activated.

Chemical reactions follow the law of mass action—that is, their speed is proportional to the product of the concentrations of the reacting substances. In most enzyme reactions the speed of decomposition of the substrate tends at first to be directly proportional to the amount of enzyme present, particularly if the substrate is present in large excess. Later the reaction may slow up due to decrease in the amount of substrate or combination of the enzyme with substrate or products of the reaction. In quantitative studies of enzyme action it is best to have a large excess of substrate and to keep the time of the experiments within the period when decomposition is proportional to time. To establish these limits an experiment must be conducted and a curve plotted showing the extent of decomposition at different time intervals. In certain cases, direct proportionality does not exist even in the early stages. In such cases a curve prepared as above will suggest the rule to be applied in the calculation of results.

### DEMONSTRATION OF THE REVERSIBLE ACTION OF AN ENZYME

The enzyme phosphorylase is found in plant and animal tissues. This enzyme catalyzes the following reaction:

The reaction is reversible and either glycogen or starch can be used to form glucose-1-phosphate (Cori ester). Whether glycogen or starch is formed from glucose-1-phosphate depends upon the source of the enzyme. Muscle phosphorylase (*in vitro*) and the phosphorylase from higher plants form a polysaccharide which is probably identical with the amylose fraction of starch. Yeast phosphorylase and the phosphorylase from liver, brain, and heart form glycogen from glucose-1-phosphate. In this case a second enzyme, the Q enzyme, is present in addition to phosphorylase. This Q enzyme forms 1–6 linkages.

The position of the equilibrium is influenced by pH. At pH 7 an equilibrium is obtained when the total phosphate is 23 per cent as Cori ester and 77 per cent as inorganic phosphate.

**1. Formation of Glucose-1-phosphate** (*Hanes method as modified by Sumner and Somers*). Boil 8 g. of soluble starch with about 100 ml. of water. Cool and add 12 g. of  $\text{Na}_2\text{HPO}_4$  and 5 g. of  $\text{KH}_2\text{PO}_4$  dissolved in about 300 ml. of water. Add 100 ml. of potato-cyanide extract. Dilute to 1 liter, add toluene, and mix. Keep at  $20^\circ$  to  $25^\circ$  C. for about 24 hours.

Inactivate the phosphorylase by adding 0.1 N iodine until the solution gives a permanent reddish-brown color. Remove the iodine by adding 0.1 N thio-sulfate until all brown color has disappeared. Add 10 to 20 ml. of 2 per cent pancreatin and allow to digest until no more dextrin remains, as shown by the iodine test. (This will take three or four hours.) Add 40 g. of barium acetate and about 8 ml. of 28 per cent ammonia, or enough to make the suspension definitely alkaline to phenol red. Mix well, centrifuge, and pour the supernatant through cotton. To each volume of supernatant add 2 volumes of 95 per cent alcohol and centrifuge down the barium salt of glucose-1-phosphate. Discard the supernatant. Stir the precipitate with 30 to 60 ml. of water and enough 2 N sulfuric acid to give a pink color with thymol blue paper. Now add saturated potassium hydroxide cautiously until the suspension just fails to give a blue or brown color with Congo red paper. Add 6 g. of trichloroacetic acid and mix. To every volume of the suspension add 2 volumes of 95 per cent alcohol and stir. Centrifuge down the suspended matter. Decant the clear supernatant solution. Add saturated potassium hydroxide to it until it is decidedly alkaline to phenol red. The di-potassium salt of glucose-1-phosphate usually separates as an oil. Chill overnight at  $0^\circ$  to  $5^\circ$  C. Next day filter off the crystals, wash several times with 95 per cent alcohol and then with acetone, and dry at  $50^\circ$  C. The yield will be about 3.5 g., and the product will be about 85 per cent pure.

The potato-cyanide is prepared by disintegrating about 325 g. of recently sliced potato in 100 ml. of 0.01 N neutralized potassium cyanide in a blender. The disintegrated mass is squeezed in cheesecloth and the juice is centrifuged to eliminate the starch.

The hexose-1-phosphate, or Cori ester, is  $\text{C}_6\text{H}_{11}\text{O}_9\text{PK}_2 \cdot 2\text{H}_2\text{O}$ . Does a trace of it reduce Benedict's solution? Heat a trace of it in boiling water for 5 minutes with 1 ml. of N sulfuric acid. Neutralize with 0.1 N NaOH. Now test for glucose. Test also for inorganic phosphate.

**2. Formation of Starch from Glucose-1-Phosphate.** Prepare 5 to 10 ml. of 0.1 per cent glucose-1-phosphate in water. Add a drop of phenol red and enough 0.1 N hydrochloric acid to bring the alkaline solution to approximate neutrality. Place 1 ml. of the solution in a test tube and add about 1 ml. of potato-cyanide extract. Add a drop of 0.01 per cent boiled starch solution and mix. This primes the reaction. From time to time remove a drop or two of the digest and test on a porcelain spot plate by adding a few drops of 0.01 N iodine solution. Is starch formed? What is the chemical reaction?

## CELL RESPIRATION

The ultimate objective in the study of those enzymes which are found within cells is to apply this knowledge to an understanding of the metabolic processes upon which the cell depends for its maintenance and function. The contributions of enzyme chemistry to this subject have been numerous and important, but it is clear that the isolation of an enzyme or enzyme activity from cells does not necessarily give information as to the significance of the enzyme in the intricate processes of metabolism within the cell. An alternate method of approach, therefore, is to study

the metabolic behavior of the isolated intact cell or tissue, under as nearly physiological conditions as possible, and to integrate knowledge gained in this way with that acquired by the study of individual enzyme systems.

It was Warburg who first showed that animal tissues and organs (liver, kidney, brain, etc.) could be prepared in the form of thin sections or minces which would continue to carry on metabolic processes (respiration, substrate utilization) for many hours after removal from the animal body if placed under suitable conditions, and that such metabolism could be followed quantitatively. While it is obvious that cells under these circumstances are no longer under the control of nervous or hormonal mechanisms, metabolic data obtained by this method of approach do not disagree with results obtained on the intact animal where the two methods can be compared, and have furnished valuable information concerning the localization of specific metabolic processes in individual organs of the animal body, as well as the effect of different substrates, coenzymes, activators, inhibitors, etc., on cell metabolism.

FIG. 79. BARCROFT-WARBURG MANOMETER WITH ATTACHED VESSEL.

In the study of isolated cells and tissues, chief attention has been directed to the respiration, and specifically to the oxygen consumption. In fact, some have defined the respiration of cells in terms of oxygen consumption alone; but carbon dioxide production is an equally important phase of respiration, and any complete characterization of cell respiration must include both oxygen consumption and carbon dioxide production. In addition to respiratory data, much valuable information has been obtained by the use of the Warburg tissue-slice technique concerning other metabolic characteristics of cells, such as substrate utilization, fermentative (glycolytic) ability, glucose and glycogen synthesis, urea formation, conjugation of foreign organic compounds, etc. The discussion in these pages will be confined to respiration and glycolysis, two characteristics of cell metabolism which are readily measured manometrically; but it cannot be too strongly emphasized that knowledge of this type is essentially incomplete until it is supplemented with precise information concerning substrate utilization and end-product formation; this fact should be more generally recognized.

**Measurement of Oxygen Consumption.** The basis of the Warburg method for the measurement of the oxygen consumption of living cells is the apparatus shown in Fig. 79. This is sometimes referred to as the Warburg apparatus, but more properly is called the Barcroft-Warburg apparatus, since it was adapted by Warburg from that developed by Barcroft for the study of blood gases. It consists of a suitable vessel, containing the material to be studied in the proper fluid medium, and attached in a closed system to a manometer for measuring changes in

gas pressure.<sup>21</sup> Various types of vessels in common use are shown in Fig. 80; many other types have been described for special purposes. In general, an ordinary Barcroft-Warburg vessel has a capacity of 15 to 20 ml., with a center well and one or more side bulbs; larger and smaller vessels have also been used. The type of bored side-bulb plug illustrated is much to be preferred over the more common solid plug.

FIG. 80. TYPES OF VESSELS USED FOR MANOMETRIC STUDIES ON CELL RESPIRATION.

To provide for accurate temperature control, manometers and vessels are so constructed that the manometer may be mounted on the side of a constant-temperature water bath (thermostat), with the vessel completely immersed in the water. To ensure equilibration between fluid medium and gas phases in a vessel during an experiment, the manometer mounting is attached to a shaking device which shakes vessel and manometer horizontally at speeds which ordinarily amount to 110–115 oscilla-

<sup>21</sup> Complete equipment of the type described here (manometers, glassware, and thermostat) may be obtained from E. Machlett and Son, New York City; Arthur H. Thomas Co., Philadelphia; or American Instrument Co., Silver Springs, Md.

tions per minute, with an excursion of 3–4 cm. A complete assembly of this type is illustrated in Fig. 81.

The detailed application of the Warburg procedure for the measurement of oxygen consumption is given in the experiments which follow this discussion. The principle is as follows: The tissue, usually in the form of thin slices, is incubated at body temperature in a suitable buffered medium, in a vessel with attached manometer, the vessel containing oxygen rather than air. The center well of the vessel contains a little strong alkali solution which absorbs any  $\text{CO}_2$  produced, so that any

FIG. 81. ASSEMBLY OF CONSTANT-TEMPERATURE BATH AND MANOMETERS AS USED FOR STUDIES ON CELL RESPIRATION.

pressure changes are due to oxygen consumption alone. The side-bulbs provide for the addition of substrate, activators, inhibitors, etc., during an experiment if desired. The gas phase in vessel and manometer capillaries is kept at constant volume; oxygen consumption is measured therefore by a fall in pressure, which is read on the manometer. The pressure readings when multiplied by a constant ("vessel constant") give the oxygen consumption, usually expressed in microliters (cubic millimeters). Readings are made at suitable intervals; they may be plotted graphically against time, or may be averaged to give the oxygen consumption over a given time interval. The standard method for expressing oxygen consumption is in terms of the number of microliters consumed in one hour by 1 mg. (dry weight) of tissue; this is symbolized by  $Q_{\text{O}_2}$ . By convention, the consumption of a gas is given a negative value. Thus a  $Q_{\text{O}_2}$  of  $-6.0$  represents the consumption of 6 microliters of oxygen per hour by 1 mg. dry weight of tissue.

Representative  $Q_{O_2}$  values for various animal tissues are given in the table on p. 340. These values must be considered approximations only, since it is known that the oxygen consumption of many tissues is affected by: the presence or absence of various substrates, the previous nutritional history of the animal, the inorganic ion composition of the medium and the type of buffer used, the length of elapsed time between the death of the animal and the start of an experiment, and even the duration of the experiment itself, since oxygen consumption may not be linear with respect to time. Despite these limitations, many valuable data have been obtained by this procedure, particularly where comparative and not absolute values are desired, as in studies on the relative effects of various substrates, coenzymes, and inhibitors, comparison between normal and abnormal tissues, etc.

A more serious limitation in the Warburg method, and one which is receiving increasing recognition, is that the tension of  $CO_2$  must be maintained at or near zero during the experiment; otherwise manometer readings will not reflect changes in oxygen content alone. This requirement means that metabolism is proceeding in the virtual absence of  $CO_2$ , and it is known that certain metabolic processes (e.g., the formation of urea by liver cells) require the presence of  $CO_2$ ; even the oxygen consumption of some tissues is significantly affected by the presence or absence of a physiological tension of  $CO_2$ . Furthermore, measurements by the Warburg method are not possible in such media as normal blood serum or other bicarbonate-containing media, since such media require the maintenance of a finite tension of  $CO_2$  to establish the pH.<sup>22</sup> For the measurement of oxygen consumption and other respiratory characteristics of tissues in the presence of physiological tensions of  $CO_2$ , the differential manometer described in the next section in connection with the measurement of  $CO_2$  production must be used.

**Measurement of Carbon Dioxide Production.** Measurement of carbon dioxide production by respiring cells or tissues is technically more difficult than is measurement of oxygen consumption. There is no satisfactory direct method for the continuous measurement of the carbon dioxide produced by cell respiration, as there is for the measurement of oxygen consumption. Hence relatively little work has been done on this phase of respiration. This is unfortunate, for, as we now know, carbon dioxide is produced not by the direct oxidation of carbon compounds by oxygen but rather by decarboxylation of organic acids, and in a manner essentially independent of oxygen consumption but presumably of equal importance to the cell. Carbon dioxide production usually is expressed by giving the value of the respiratory quotient (R.Q.), which is the ratio of the volume of carbon dioxide evolved to the volume of oxygen consumed in the same time; hence if the  $Q_{O_2}$  and R.Q. are given, the carbon dioxide production is defined.

One method for the determination of R.Q. in phosphate buffer using

---

<sup>22</sup> For measuring oxygen consumption by the Warburg method in "neutralized" serum—i.e., serum which has been freed of bicarbonate by treatment with acid and evacuation—see Macleod and Rhoads: *Proc. Soc. Exptl. Biol. Med.*, **41**, 268 (1939); Warren: *Am. J. Physiol.*, **128**, 455 (1940).

the ordinary Barcroft-Warburg manometers is to set up duplicate tissue preparations but to omit the alkali from the center well of one vessel. Pressure changes in the vessel containing alkali are due to oxygen consumption alone; pressure changes in the second vessel, without alkali, represent the net (and opposing) effects of oxygen consumption and carbon dioxide production. At the end of the experiment, by subtracting

the pressure change due to oxygen consumption alone, as established on the first manometer, from the reading of the second manometer, the pressure change due to carbon dioxide production may be obtained. Conditions in the two vessels, including vessel constants, must be as nearly alike as possible. This, of course, cannot be true with respect to the  $\text{CO}_2$  tension, which is zero in the first vessel and continuously increasing in the second vessel. Results will therefore be in error if the  $\text{CO}_2$  tension influences metabolic processes within the cell, and this is known to be the case with a number of different types of cells. This method is therefore not widely used.

It is also possible to so arrange matters that only one vessel containing alkali is used, and the  $\text{CO}_2$  absorbed by the alkali is measured by liberating with acid at the end of the experiment. This method is technically quite difficult, is not too accurate, and likewise suffers from the disadvantage that measurements are made in the presence of a zero  $\text{CO}_2$  tension.

To permit measurement of carbon dioxide production (and oxygen consumption as well) in the presence of a physiological tension of carbon dioxide, and therefore in media such as blood serum or Ringer-bicarbonate solution which are more nearly physiological than phosphate or similar buffers, various types of so-called differential manometers have been developed. One such type<sup>23</sup> is illustrated in Fig. 82. It consists of two independent vessels and manometers, with the manometers so arranged that pressure changes in the two vessels may be opposed to one another on the manometer, to permit precise measurement of the pressure differences between the vessels rather than the total pressure in

each. In use, the two vessels are charged with identical amounts of medium and tissue, the medium being either blood serum or Ringer-bicarbonate, and the gas phase being oxygen containing a physiological concentration (usually 5 per cent) of carbon dioxide. At the beginning of the experimental period, the tissue in one vessel is killed by tipping in acid from a side bulb, and the tissue in the other vessel is then allowed to respire for the desired length of time, after which it too is killed by the addition of acid. Although the total pressure in both vessels is now quite high, due to the liberation of  $\text{CO}_2$  from the decomposed bicarbonate in the medium,

FIG. 82. CONSTANT-VOLUME DIFFERENTIAL MANOMETER.

<sup>23</sup> Summerson: *J. Biol. Chem.*, 131, 579 (1939).

by opposing one vessel pressure against the other on the manometer only the difference in pressure caused by the respiration of the tissue in the second vessel during the experimental period will register on the manometer. This pressure difference is due to both oxygen consumption and carbon dioxide production. After it is noted, alkali is admitted into both vessels through a bottom stopcock (see Fig. 80 for the type of vessel used) and all the carbon dioxide is absorbed. Again the differential reading is noted; this is now due solely to oxygen consumption by the respiring tissue. The carbon dioxide production is obtained by subtracting this reading from the first differential reading. Thus the oxygen consumption and R.Q. are accurately measurable under a continuous physiological tension of carbon dioxide. The only disadvantage of this method over the simple Warburg method as far as oxygen consumption measurements are concerned is that the Warburg method gives continuous readings, whereas the differential method gives but one reading, representing the entire experimental period. Conditions, therefore, must be selected so that respiration is linear with respect to time, or nearly so.

The use of the differential manometer is technically somewhat more difficult than is that of the simple Barcroft-Warburg manometer, but it is the only accurate basis for the measurement of cell respiration under conditions which closely simulate those prevailing normally, and the increased significance of the results obtained more than justifies the technical difficulties.

A further advantage of the differential manometer is that it permits the measurement of aerobic acid production (*aerobic glycolysis*, see below) by respiring tissues. If the tissue produces acid—e.g., lactic acid—aerobically in a medium containing bicarbonate, neutralization of the acid results in the decomposition of an equivalent amount of bicarbonate to produce gaseous  $\text{CO}_2$ . This  $\text{CO}_2$  is indistinguishable manometrically from the  $\text{CO}_2$  of respiration unless the differential manometer is used, where it is readily done by a simple method which need not be described here (for details see Summerson (*loc. cit.*) and also books by Dixon and by Umbreit, et al., cited in the Bibliography). Since the production of acid aerobically is a characteristic which differentiates tumor tissues from many (but not all) normal tissues (see table on p. 340), the differential manometer is useful in metabolic studies on such tissues.

**Anaerobic and Aerobic Glycolysis.** Practically all tissues show the ability to produce lactic acid from either glucose or glycogen under anaerobic conditions. Such production of lactic acid is known as glycolysis, although strictly speaking this term implies merely a disappearance of carbohydrate rather than the specific production of lactic or other acids. With certain tissues—e.g., liver, kidney—the anaerobic formation of lactic acid is at the expense of tissue glycogen and is independent of the presence of glucose; it has been proposed that the term *glycolysis* be restricted to such origin of lactic acid from glycogen, and that the term *glucolysis* be used where glucose is the source of the lactic acid.

Anaerobic glycolysis by tissues is readily measured with the simple Barcroft-Warburg manometers by suspending the tissue in a bicarbonate-containing medium in equilibrium with the proper tension of  $\text{CO}_2$  in the

gas phase to maintain a suitable pH, but with nitrogen rather than oxygen present. Since in the absence of oxygen there is no respiration, pressure changes on the manometer will ordinarily be due solely to decomposition of bicarbonate by the acid produced anaerobically. Anaerobic glycolysis usually is represented by the symbol  $Q_G^{N_2}$ , and is expressed in terms of microliters of  $CO_2$  produced by the action of acid on the bicarbonate present, per milligram dry tissue per hour. The anaerobic glycolytic power of various animal tissues is given in the table below. No distinction is made in this table between glucolysis and glycolysis, and the values for certain tissues such as liver and kidney are subject to considerable variation because the rate of glycolysis usually falls off continuously throughout the average experimental period. It will be noted that various tissues differ considerably in their  $Q_G^{N_2}$  values, and that tumor tissues in general (but not exclusively) are quite high in this respect.

\* Many values are averages from the literature. For significance of symbols used, and further discussion, see text.

The production of acid aerobically is also measurable in terms of the decomposition of bicarbonate, is symbolized by  $Q_G^{O_2}$ , and expressed in the same units as for anaerobic glycolysis. Aerobic glycolysis is more difficult to measure than anaerobic glycolysis, since there must be a way to differentiate the  $CO_2$  of acid production from the respiratory  $CO_2$ . The only successful way to do this is with the differential manometer, as discussed previously. In contrast to acid production anaerobically, which in the majority of cases is quantitatively due to lactic acid, only a fraction of the acid produced aerobically is usually accountable for as lactic acid. Little specific information is available concerning the nature of other acids produced under these circumstances. As can be seen from the data above, most normal adult tissues have a relatively low aerobic glycolysis; certain specialized normal adult tissues, and all tumor tissues, are characterized by a significant aerobic glycolysis.

It is felt by some that the inhibition of anaerobic glycolysis (“fermentation”) by aerobic metabolism, which is called the *Pasteur effect*, may be associated with the presence of a specific enzyme (*Pasteur enzyme*) whose function is to orient cell metabolism into either fermentative or oxidative pathways. Evidence for the existence of such an enzyme is limited at the present time.

EXPERIMENTS ON CELL RESPIRATION

**1. Calibration of Vessel and Manometer: Principle.** For the calculation of changes in gas content in a vessel from the manometer readings, under a particular set of experimental conditions, it is necessary to know the entire volume of gas space in the empty vessel, manometer side-arm, and manometer capillary down to the level of manometer fluid as it will be placed in actual use. The best way to do this is by filling the entire space with mercury, then collecting and weighing the mercury; from the known density of the mercury at the temperature of use, the volume occupied by the mercury is readily obtained.

**Procedure.** (a) Place the manometer (clean, dry, and empty of manometer fluid) in an upright position. Fill the clean dry vessel with mercury, being sure that the vessel side tap is firmly in place (it may be lightly greased and held secure by springs or wound rubber bands). The mercury must fill the entire vessel including the center well and side bulb; any trapped air bubbles may be dislodged with a piece of fine wire. The mercury should come to within about one-half inch of the top rim of the vessel. Holding the vessel in the hand, set it slowly in place on the manometer side arm until it is firmly seated. Excess mercury will run out between vessel and manometer ground-glass surfaces during this process, should be brushed off if adhering to the glass, and may be caught in a large tray set beneath the entire assembly for this purpose. A thread of mercury will likewise be forced up into the capillary of the manometer side arm for a variable distance. When the vessel is firmly seated on the manometer, make a mark on the manometer side arm to indicate the limit of the mercury thread. The best position for this is in the straight portion of the side-arm capillary a few centimeters above the vessel; other vessels may then be calibrated on this same manometer in the future, without the necessity of removing any manometer fluid present, by adjustment of the mercury thread to the same mark; this adjustment is particularly easy if the vessel side-bulb tap is bored as shown in Fig. 80, since by turning the tap to open it slightly, by slight pressure or suction the mercury level in the manometer side-arm capillary may be controlled at will.

When the mark has been made, slowly withdraw the vessel from the manometer, allowing the capillary thread of mercury to follow and be caught in the mercury in the vessel as it is removed from the manometer. Transfer the mercury from the vessel to a tared beaker, and weigh the mercury to the nearest 0.1 g. Note the temperature of the mercury. From the volume occupied by 1 g. of mercury at the indicated temperature,<sup>24</sup> calculate the

<sup>24</sup> The volume occupied by 1 g. of mercury at various temperatures is as follows:

| Temp.<br>°C. | Volume<br>ml. | Temp.<br>°C. | Volume<br>ml. |
|--------------|---------------|--------------|---------------|
| 16           | 0.07377       | 24           | 0.07388       |
| 18           | 0.07379       | 26           | 0.07390       |
| 20           | 0.07382       | 28           | 0.07393       |
| 22           | 0.07385       | 30           | 0.07396       |

volume occupied by the mercury at this stage of the calibration. Call this volume  $V_V$ .

(b) Invert the manometer, turn it so that the front faces to the right and the side arm projects to the left, and fasten it securely in an upright position with a large adjustable buret clamp attached to a ring stand. Now loosen the attachment of the buret clamp to the ring stand and tilt the manometer clockwise until the calibration mark on the side arm and the 150-mm. graduation mark on the attached manometer limb are in line with each other and parallel to the table top. Clamp the manometer firmly in this position. Attach to the side orifice of the manometer stopcock a piece of rubber tubing carrying a screwcock and connected to a leveling bulb containing mercury. The manometer stopcock should be lightly greased and may be held secure by rubber bands. Turn the manometer stopcock so that mercury may enter from the rubber tubing and rise into the manometer capillaries. By carefully releasing the screwcock on the rubber tubing, allow mercury to enter the manometer capillaries and rise in the side arm and main limb until the mercury level reaches both the calibration mark on the side arm and the 150-mm. graduation on the main limb. Slight further tilting of the manometer may be necessary at this point. If there are any trapped air bubbles, lower the leveling bulb to retract the mercury and repeat the adjustment.

When both capillaries of the manometer are filled with mercury to the desired points, turn the manometer stopcock very slightly to cut off the flow of mercury, place a tared beaker under the straight capillary orifice of the manometer stopcock, and then turn the stopcock so that the mercury drains from the manometer capillaries into the beaker. Any droplets of mercury remaining behind may be forced out and into the beaker by blowing down the capillaries. Weigh the mercury, determine its temperature, and calculate the volume of the side-arm and main limb capillaries. Call this volume  $V_M$ .

CALCULATION. The total volume of empty vessel and manometer gas space,  $V_T$ , is equal to  $V_V + V_M$ . From the value of  $V_T$ , the vessel constant  $k$  under a particular set of experimental conditions is calculated as follows:

$$k = \frac{V_T}{P_o} \cdot \frac{273}{T} - \frac{V_F}{P_o} \left( \frac{273}{T} - \alpha \right)$$

where  $V_T$  is the total volume of vessel and manometer, as described above, and  $V_F$  is the volume of fluid medium in the vessel during an experiment; both of these volumes are expressed in microliters (cubic millimeters) rather than in milliliters (1 ml. = 1000 microliters).  $P_o$  is the equivalent of 1 atmosphere pressure in mm. of manometer fluid (760 for mercury, 10,000 for Brodie fluid; see below),  $T$  is the temperature in degrees Absolute at which measurements are made, and  $\alpha$  is the absorption coefficient (solubility) of the gas undergoing absorption or evolution.<sup>25</sup> For the derivation of this equation, see the book by Dixon; the form of the equation is that described by Macleod and Summerson.<sup>26</sup>

It can be seen that the constant for a particular vessel and manometer depends upon the size of the vessel, the volume of medium used, the temperature, and the nature of the gas concerned. The following example illustrates the calculation of the vessel constant for oxygen,  $k_{O_2}$ , for a particular vessel and manometer where  $V_T = 15.75$  ml. and 2.0 ml. of medium are employed, at 38° C.

<sup>25</sup> At 38° C.,  $\alpha$  for  $O_2$  is 0.024; for  $N_2$ , 0.012; and for  $CO_2$  in water 0.55; in Ringer solution, 0.537, and in Ringer solution containing 0.3 N HCl, 0.517. For values of other gases and at other temperatures, see handbooks giving physical constants of gases.

<sup>26</sup> Macleod and Summerson: *Science*, **91**, 201 (1940).

$$V_T = 15.75 \text{ ml.} = 15,750 \mu\text{l.}$$

$$V_F = 2.00 \text{ ml.} = 2,000 \mu\text{l.}$$

$$T = 38^\circ \text{ C.} = 311^\circ \text{ A.}$$

$$P_o = 10,000$$

$$\alpha_{O_2} = 0.024 \text{ at } 38^\circ \text{ C.}$$

therefore

$$\begin{aligned} k_{O_2} &= \frac{15,750}{10,000} \times \frac{273}{311} - \frac{2,000}{10,000} \left( \frac{273}{311} - 0.024 \right) \\ &= 1.38 - 0.17 \\ &= 1.21 \end{aligned}$$

The vessel constant will be different with other amounts of medium, at other temperatures, and for other gases. For routine work on oxygen consumption at  $38^\circ \text{ C.}$ , the only variable is likely to be the volume of medium employed. Vessel constants should therefore be calculated for the various volumes of medium apt to be used, or the simple graphical method described by Macleod and Summerson (*loc. cit.*) for this purpose may be employed.

The calibration is described for a manometer fluid setting at the 150-mm. mark on the graduated limb. This is the most satisfactory position, but calibration obviously can be made to some other setting. If a thread of mercury is placed in the graduated capillary, the length in mm. noted, and the mercury then weighed and its volume computed, the volume of the graduated capillary per mm. may be obtained, and from this it is possible to calibrate the manometer at any setting on the scale provided the calibration at one setting is also known. This is of value under certain circumstances.

**MANOMETER FLUID.** The most commonly used manometer fluid is the aqueous salt solution described by Brodie<sup>27</sup> with a specific gravity of 1.033, so that 10,000 mm. are equal to 1 atmosphere (760 mm. of mercury); this makes for obvious convenience in calculation, with a much greater sensitivity than mercury. For special purposes, however, any other fluid whose  $P_o$  value is known (water, mercury, paraffin oil, etc.) may be used.

The manometer fluid usually is contained in a stoppered rubber tube attached to the manometer which acts as a reservoir, controlled by the pressure of a screwcock. The fluid may gradually leak out or be otherwise lost; it may be replenished at any time, even during an experiment, by inserting a hypodermic needle attached to a syringe containing extra fluid through the rubber tube wall, at a slight angle to form a "Bunsen valve" after withdrawal of the needle. It may also be added through the open top of the manometer, with precautions to avoid trapping air bubbles. Should such bubbles be present, they may be forced to the top of the fluid column and dissipated by alternate pinching and release of the rubber tube reservoir with the fingers, to force the manometer fluid up and down.

## 2. Measurement of Oxygen Consumption of Rat Liver Slices by Warburg:

**Method.** (a) PREPARATION OF TISSUE. Kill a young adult rat by a blow on the

<sup>27</sup> Brodie fluid is made as follows: Dissolve 23 g. of sodium chloride and 5 g. of bile salts (sodium tauroglycocholate, or sodium glycocholate, Merck) in 500 ml. of water. A few drops of an alcoholic thymol solution may be added as a preservative, and it is convenient to color the fluid by adding a few hundred mg. of a suitable dye (Crystal violet, Gentian violet, or Evans blue). The specific gravity of the final solution should be 1.033; i.e., 10 ml. should weigh 1.033 times as much as 10 ml. of water at the same temperature.

head, followed by severing the neck vessels and spinal cord at the neck with scissors. Open the abdominal cavity and remove the liver as quickly as possible. Rinse the liver in a beaker containing Ringer's solution,<sup>28</sup> then cut off the largest lobe of the liver and place flat on a pad of filter paper to drain momentarily. With a sharp thin razor blade moistened with Ringer's solution, cut off a small portion of the liver in such a way that the cut surface makes an angle of about  $45^\circ$  with the table top, and discard this portion. Continue cutting freehand along the plane of the first cut surface to obtain a number of thin slices of liver, making each slice as uniformly thin as possible (the leading edge of the razor blade should be visible through the slice as it is being cut). With practice, uniform slices about 0.5 mm. thick are readily obtained. As each slice is obtained, transfer it to a flat dish containing Ringer's solution, and keep the blade of the razor and the cut surface of the liver moistened with Ringer's solution. Continue cutting until sufficient slices for the experiment are obtained; usually two to four slices are required per vessel.

(b) PREPARATION OF VESSELS. Measure duplicate (or triplicate) 2-ml. portions of medium<sup>29</sup> into clean dry Barcroft-Warburg vessels, avoiding the center well. In another vessel place a few ml. of water; this will be the thermobarometer control. With a forceps or platinum wire, transfer a liver slice from the dish to a pad of filter paper and drain momentarily, then quickly transfer to a tared watch glass on a balance. Add more slices treated in the same way until the desired weight of liver tissue is obtained; 100 to 200 mg. wet weight is usually satisfactory. Immediately transfer the weighed clump of slices to one of the vessels, immersing them in the medium. The vessel may be shaken briefly to separate the slices. In like manner, charge the remaining vessels containing medium with weighed amounts of tissue. The weights of tissue in each vessel need not be identical, but they should be known to the nearest milligram.

When all the vessels are ready, obtain one more known weight of tissue by exactly the same procedure, but transfer this to a small tared watch glass or weighing dish. This is to be dried in an oven overnight at  $100^\circ\text{C.}$ , and weighed again, to determine the dry weight of the tissue.

When the tissue is in place in the vessels, complete the preparation of the vessels by placing in the center well of each (except the thermobarometer vessel) 0.2 ml. of 10 per cent KOH solution, using a pipet with a fine tip. No alkali must get into the medium surrounding the center well. It is advantageous, but not absolutely necessary, at this point to insert a small roll of starch-free filter paper (Whatman No. 40 is satisfactory) in the center well so that the top of the roll projects a millimeter or two above the rim of the center well; the alkali, being absorbed on the paper roll, thus projects into the gas space of the vessel and is better able to absorb  $\text{CO}_2$ .

(c) PREPARATION OF MANOMETER. When all the vessels are ready, mount each one on its manometer, using a small amount of suitable stopcock grease,<sup>30</sup>

---

<sup>28</sup> Ringer's solution may be prepared as follows: to 960 ml. of 0.154 M NaCl solution add 20 ml. of 0.154 M KCl solution and 20 ml. of 0.11 M  $\text{CaCl}_2$  solution.

<sup>29</sup> The usual medium is Ringer-phosphate. To 10 volumes of Ringer's solution add 1 volume of M/15 phosphate buffer, pH 7.4. For preparation of phosphate buffer, see Chapter 1. If glucose is desired in the medium, a level of 200 mg. per 100 ml. may be established by adding 2 ml. of 10 per cent glucose solution to 100 ml. of medium. The presence of glucose in the medium does not affect the oxygen consumption of liver slices, but is necessary with many other tissues.

<sup>30</sup> "Cello-Seal," obtainable from the Fisher Scientific Co., New York, is quite satisfactory. Ordinary petroleum jelly or anhydrous lanolin may also be used, but since these

and attaching the vessels firmly to the manometer shanks by small springs or wound rubber bands. Fill each vessel containing tissue with oxygen by passing a slow stream of the washed gas from a tank<sup>31</sup> through the vessel, attaching the rubber tube delivering the gas to the top of the manometer so that the gas passes through the manometer stopcock and capillaries into the vessel and out the opened side bulb of the vessel. A few minutes' passage is sufficient for each vessel; all the vessels can be gassed at once if a multiple manifold attached to the tops of all the manometers is used. It is not necessary to gas the thermobarometer vessel.

When the vessel is filled with oxygen, turn the stopcock at the top of the manometer so as to close off the manometer and divert the flow of gas to the outside air; at the same time, have the greased plug for the side bulb ready, and as soon as the gas flow has been diverted, insert this plug and fasten it securely. Continue in this way with each of the other vessels being gassed.

Place the manometers one by one on the constant-temperature bath, which should be at 38° C. As each vessel enters the thermostat, the temperature rise will cause expansion of the enclosed gas and the manometer fluid will rise. Release the excess pressure by momentarily opening the manometer stopcock to the air and then closing it. This operation may have to be repeated. The thermobarometer is placed on the bath with the manometer stopcock open.

Start the shaking device and shake vessels and manometers for 10 minutes; this is usually sufficient to bring about temperature and pressure equilibrium. During this time, adjust the manometer fluid so that the level in the closed limb is approximately at the calibration setting (usually the 150-mm. point on the scale). Since the pressure change to be expected during the experiment will be negative, the level of manometer fluid in the open limb should be as high as possible, to permit maximum range of readings. It may be necessary here also to release the pressure within a vessel momentarily to permit the indicated adjustment of manometer fluid level in each limb. During the preliminary equilibrium period, close the thermobarometer also; the level of manometer fluid should be about the same in each limb here.

When measurements are to be begun, stop the shaking device, note the time, and immediately set the manometer fluid level in the inner (closed) limb of the first manometer at exactly 150 mm. Record the fluid level in the open limb, to the nearest mm. Now read the thermobarometer in the same way. For each vessel reading there must be a thermobarometer reading unless temperature and atmospheric pressure remain sufficiently constant so that one thermobarometer reading suffices for all the vessels; this is rarely true.

Continue with the reading of the second manometer in the same way, until all of the manometers containing tissue have been read. When this has been done, start the shaking device. Repeat the readings as above, at suitable time intervals, usually 10 or 15 minutes, for the duration of the experimental period.

**CALCULATION.** Subtract each reading for a vessel from the previous reading, and from this subtract algebraically the change in thermobarometer reading during the same time, to obtain the net change in pressure for the time interval covered by the readings. Multiply the pressure change,  $h$ , by the vessel constant for oxygen under

---

become somewhat soft at 38° C., it usually is necessary to tighten the vessels on the manometers at least once during the preliminary incubation period when they are used.

<sup>31</sup> Tanks containing oxygen and other gas mixtures mentioned here may be obtained from the Ohio Chemical Co., New York City.

the particular experimental conditions,  $k_{O_2}$ , to obtain the oxygen consumption in microliters. Multiply this by  $\frac{60}{t}$ , where  $t$  is the time in minutes, and divide the result by the dry weight of the tissue, in mg., to obtain the  $Q_{O_2}$  value for the tissue.

(1) 
$$h \times k_o = X_o$$

(2) 
$$X_{O_2} \times \frac{60}{t} \times \frac{1}{\text{dry weight}} = Q_{O_2}$$

*Example.* The protocols of a typical experiment are illustrated as follows:

| READINGS                  |                            |                              |                   |
|---------------------------|----------------------------|------------------------------|-------------------|
| <i>Time<br/>(Minutes)</i> | <i>Manometer<br/>No. 1</i> | <i>Thermo-<br/>barometer</i> | <i>Net Change</i> |
| 0                         | 282                        | 151                          |                   |
| 15                        | 260                        | 153                          |                   |
|                           | -22                        | 2                            | -24               |
| 30                        | 238                        | 150                          |                   |
|                           | -22                        | -3                           | -19               |
| 45                        | 211                        | 146                          |                   |
|                           | -27                        | -4                           | -23               |
| 60                        | 190                        | 146                          |                   |
|                           | -21                        | 0                            | -21               |
|                           |                            |                              | -87 for 1 hr.     |

$$h = -87$$
$$k_{O_2} = 1.43 \text{ at } 2 \text{ ml. } V_F$$
$$X_{O_2} = 1.43 \times -87 = -124 \text{ }\mu\text{l.}$$

Wet weight of tissue = 98 mg.

% solids in tissue = 24.3

$$\text{Dry weight of tissue} = 98 \times 0.243 = 24 \text{ mg.}$$
$$Q_{O_2} = -124 \times \frac{60}{60} \times \frac{1}{24} = -5.2$$

The per cent of solids in the slices is obtained from the weight before and after drying overnight in an oven at 100° C. The water content of tissue slices stored in Ringer's solution is not necessarily the same as that of the original fresh tissue. Many of the data in the literature are based upon dry weights obtained by removing the slices from a vessel at the end of the experiment, draining, drying, and weighing. Results by this method usually are considerably higher than those obtained on the basis of the "initial" dry weight as described here, and may be seriously in error, particularly if (as usually happens), the slices disintegrate to some extent during an experiment. Results are occasionally reported on some basis other than the dry weight, such as in terms of milligrams of protein nitrogen, etc. The dry-weight procedure is most commonly followed.

With vessel constants of approximately 1.5, and a manometer scale length of 300 mm., it usually is possible to measure the absorption of about 400  $\mu$ l. of oxygen without resetting the manometer. If it is wished to continue measurements beyond this point, the manometer may be reset by opening the manometer stopcock momentarily to admit a little air, closing it, and then adjusting the fluid level in the closed limb to the 150-mm. mark again, and reading the new level of fluid in the open limb against the thermobarometer as usual, continuing with the readings as described in the pro-

cedure above. If at the end of an experimental period the fluid level in the open limb is below the graduated range when the manometer is set at 150 mm., and it is desired to obtain a reading without resetting the manometer, set the manometer level at two successive points above the 150 mark—e.g., at 170 and at 160—make each reading quickly, and extrapolate to the reading at 150, since the change in reading between 160 and 150 will be the same as that between 170 and 160.

**3. Measurement of Anaerobic Glycolysis by Tissues.** Prepare the tissue as described under Exp. 2, but use Ringer-bicarbonate solution containing added glucose as the medium<sup>32</sup> and do not put any alkali into the center wells. After attaching the vessels to the manometers, pass a stream of washed nitrogen gas containing 5 per cent carbon dioxide<sup>33</sup> through the vessels for 20 to 30 minutes at room temperature to completely displace any oxygen present. During the gassing period run the manometer fluid up and down once or twice to replace the air in the manometer capillary by the gas mixture, and shake the vessels occasionally to aid in displacing any air bubbles trapped in the medium. In turning the gas off and closing the vessels, take suitable precautions against the possible diffusion of room air into the system in the process. Vessels with bored plugs in the side bulbs, which can be left in place but clear for the passage of gas during the gassing period, and then closed by a quarter-turn, are much to be preferred over the type having solid side-bulb plugs.

The rise in pressure caused by immersing the vessels in the thermostat at 38° is released as described under Exp. 2, again with precautions against allowing air to reënter the system. Since the readings will always be positive in this type of experiment (i.e., the pressure will increase owing to decomposition of bicarbonate by the acid produced), set the manometer fluid level in the open limb at the bottom of the scale rather than at the top. This is easily done by forcing up the manometer fluid in the closed limb to about 200 mm., opening the stopcock cautiously to release most (but not all) of the excess pressure; then closing the stopcock and lowering the manometer fluid level to the 150 mark on the closed limb. If this is done properly, the fluid level in the open limb will be low down on the scale at this point.

Equilibrate by shaking for 10 minutes; then start readings, making them against a thermobarometer (which need not be gassed) just as described for the measurement of oxygen consumption in Exp. 2. Read at suitable intervals for the desired length of time.

**CALCULATION.** Subtract each reading from the next one, and subtract algebraically from this the change in thermobarometer reading during the same period, as for Exp. 2, to obtain the net increase in pressure due to acid production. Multiply by the vessel constant for CO<sub>2</sub> at the fluid volume used,  $k_{\text{CO}_2}$ , to obtain the number of  $\mu\text{l.}$  of CO<sub>2</sub> evolved as the result of acid production. Express results in terms of  $Q_G^{\text{N}_2}$ , which is defined as the number of microliters of CO<sub>2</sub> equivalent to the acid produced by 1 mg. dry weight of tissue in one hour, under anaerobic conditions.

---

<sup>32</sup> To 5 volumes of Ringer's solution add 1 volume of 0.15 M NaHCO<sub>3</sub> solution. Bubble the nitrogen (95 per cent)–CO<sub>2</sub> (5 per cent) gas mixture through this solution for about 15 minutes before using, to bring to pH 7.4. A glucose concentration of approximately 200 mg. per 100 ml. may be established by adding 2 ml. of 10 per cent glucose solution to each 100 ml. of medium.

<sup>33</sup> Tanks containing 95 per cent nitrogen–5 per cent carbon dioxide gas mixture may be obtained from the Ohio Chemical Co., New York City. The gas mixture may be freed from the traces of oxygen usually present by passing through a heated tube filled with metallic copper turnings. Pass the dried gas through a wash bottle containing water to saturate with water vapor before entering the vessels.

With certain tissues anaerobic glycolysis proceeds linearly for hours, provided sufficient glucose is present; with other tissues the rate of glycolysis is independent of the presence of glucose (and hence is presumably at the expense of glycogen) and may show a continual decrease with time. In this latter instance, the  $Q$  values represent the average for an hour, or may be computed on the basis of shorter experimental periods.

## Salivary Digestion

**Digestion in General.** The greater part of the food elements in the diet require special treatment to render them capable of absorption and utilization by the body. Water, glucose, and certain inorganic salts and vitamins are exceptions, but the proteins, fats, and carbohydrates, as well as other substances, must be split up into simple components as monosaccharides, glycerol, fatty acids, amino acids, etc. The necessary changes are chiefly hydrolytic in character and involve especially the action of enzymes found in the different parts of the gastrointestinal tract. Because of the variations in the quantity and character of food ingested and the variety of changes that must be brought about, the different parts of the gastrointestinal tract must show a considerable power of adaptation and coördination. In this, both hormone and nervous mechanisms are concerned.

Certain changes similar to those occurring in digestion may take place in foods prior to ingestion. In the ripening of certain fruits, such as the banana, starch is changed to dextrin and maltose through the action of amylase. Meats on storage undergo some self-digestion or autolysis. This process may be hastened for commercial purposes ("tenderizing") by the application of proteolytic enzyme preparations to meat cuts. In the cooking of foods connective-tissue fibers are gelatinized and starch granules are broken up and some dextrinization of starchy foods occurs. Cooking also increases the palatability of foods and in this way promotes the secretion of digestive juices.

**Secretion of Saliva.** The saliva is secreted by three pairs of glands—parotid, submaxillary, and sublingual—reinforced by numerous small glands called buccal glands. These secretions vary in character. Thus in man the parotid saliva is watery and has a high digestive power. The secretions of the other glands are higher in mucin and more viscid. Ordinary saliva is a mixture of the secretions of these glands and shows considerable variations in composition in different individuals, and in the same individual at different times.

The secretion of saliva is governed by a set of nerve fibers cerebral in origin, together with fibers from the sympathetic nervous system. No hormone mechanism in salivary secretion is known. Ordinarily the secretion of saliva is the result of a reflex stimulation of the secretory nerves through a center in the medulla oblongata. Psychic stimuli, brought about by such influences as the thought of food, pass from the higher nerve centers to the secretory center and also give rise to secretion. The

results of Pavlov on dogs show it to be rather difficult in certain cases to differentiate between the two types of stimuli. Pavlov found that dropping several pebbles into a dog's mouth caused the flow of but one or two drops of saliva, but sand in the mouth induced a copious flow of a thin watery saliva. Ice water caused no secretion, but acid or bitter solutions which the animal wished to reject caused a free flow of saliva. Dry food caused the secretion of a watery saliva; meat led to the flow of a more slimy secretion, such as would aid in the lubrication of this food for swallowing. Drawing the attention of the animal to these foods, without actually giving them to him, gave rise to similar secretions. Thus, also, the pretense of throwing sand into the mouth of the dog gave rise to a profuse watery secretion.

The amount of saliva secreted by an adult in 24 hours has been variously placed, as the result of experiment and observation, between 1000 and 1500 ml., the exact amount depending, among other conditions, upon the character of the food. In the absence of obvious external stimuli, the rate of salivary secretion in the adult appears to be between 0.1 ml. and 0.9 ml. per minute.

**Composition of Saliva.** Salivary composition depends on many factors: stimulation, diet, age, time of day, disease, etc. To insure reproducible, representative samples for analysis, the conditions for collection should include (a) a definite physiological, postabsorptive state (before breakfast), (b) no brushing of the teeth, rinsing of the mouth, or smoking prior to collection, (c) about a two-hour interval between arising and collection, including a 15-minute rest period immediately preceding collection. Stimulation yields a relatively more dilute saliva, but the difference diminishes as collection is prolonged.

Ordinarily saliva varies from weakly alkaline to weakly acid, the pH ranging approximately from 6.0 to 7.9 with an optimum pH of 6.6. There is evidence that normal individuals under 20 and without dental defects secrete a saliva with a pH between 7.0 and 7.2. No absolute correlation has been shown between salivary acidity and caries or other dental disorders. However, lower pH values occur more frequently among caries-susceptible individuals. There is evidence that increased acidity of saliva is a late rather than early manifestation of the caries syndrome as compared with changes in the level of other salivary constituents. Dental erosion is usually accompanied by greatly increased total salivary acidity. The acid secretion from the gingival crevice and the marginal gingiva tends to dissolve enamel in the regions already predisposed as a result of unfavorable metabolic conditions.

Saliva is a dilute secretion having an average specific gravity of 1.007 with about 0.7 per cent of solid matter, about 0.5 per cent being organic and 0.2 per cent inorganic. Of the organic matter about 0.4 per cent is protein, chiefly mucin, with small amounts of albumin and globulin. Other organic constituents are enzymes (chiefly salivary amylase), urea, uric acid, cholesterol, vitamins, and phospholipide. Average values have been reported of total nonprotein nitrogen 13 mg., urea plus ammonia nitrogen 11 mg., and uric acid 1.5 mg. per 100 ml. These amounts averaged 37 per cent, 76 per cent, and 40 per cent, respectively, of the cor-

responding constituents in blood. Analyses of the saliva for these constituents possess a certain clinical value in the study of nephritis but are little used for this purpose. Normal saliva contains no glucose. Increases in cholesterol and in lipide phosphorus have been noted in certain dental disorders.

The normal composition of saliva is shown in the accompanying table.

COMPOSITION OF NORMAL SALIVA\*

| Constituent                              | Normal Range |   |                       |
|------------------------------------------|--------------|---|-----------------------|
| Acidity (pH).....                        | 6.0          | — | 7.9                   |
| Titratable alkalinity (as 0.02 N HCl)... | 90.0         | — | 190.0 ml. per 100 ml. |
| Ammonia N.....                           | 2.0          | — | 10.0 mg. per 100 ml.  |
| Calcium, total, as Ca.....               | 4.0          | — | 8.0 mg. per 100 ml.   |
| Inorganic phosphate, as P.....           | 10.0         | — | 25.0 mg. per 100 ml.  |
| Chloride, as Cl.....                     | 30.0         | — | 60.0 mg. per 100 ml.  |
| Carbonate, as CO <sub>2</sub> .....      | 20.0         | — | 45.0 ml. per 100 ml.  |
| Protein.....                             | 200.0        | — | 400.0 mg. per 100 ml. |
| Cholesterol.....                         | 2.5          | — | 9.0 mg. per 100 ml.   |
| Lipide P.....                            | 0.05         | — | 0.20 mg. per 100 ml.  |

\* The values here given are based on saliva collected in a postabsorptive state, and (with the exception of those for cholesterol and lipide P) by stimulation. Possible relationship to caries may be found in the following constituents: ammonia, calcium and phosphate (especially the adsorbable fractions), carbonate, cholesterol, and lipide P. Acknowledgment is made to Dr. Frances Krasnow for the data from which this table was compiled.

Potassium thiocyanate, KSCN, is also generally present in the saliva to the extent of several milligrams per milliliter. The significance of thiocyanate in the saliva is not known; it may possibly come from the ingested cyanides present in certain fruits and in tobacco smoke and from the breaking down of protein material. *Apoerythein*, a protein fraction which protects vitamin B<sub>12</sub> from digestive destruction is also present in saliva. This may be identical with the *intrinsic factor of Castle*.

Dam and his associates<sup>1</sup> have shown the following average content of vitamins in saliva (gamma (γ) per ml.): Thiamine 0.007, riboflavin 0.05, niacin 0.03, pyridoxine 0.6, pantothenic acid (as Ca salt) 0.08, folic acid 0.0001, biotin 0.0008, ascorbic acid 2.4, vitamin K (as menadione) 0.015.

The so-called tartar formation on the teeth is composed almost entirely of calcium and magnesium phosphates with some calcium carbonate, mucin, epithelial cells, and organic debris derived from the food. The calcium salts are held in solution as acid salts, and are probably precipitated by alkalinity caused by ammonia formation through bacterial action or through loss of CO<sub>2</sub> from the saliva. The various organic substances just mentioned are carried down in the precipitation of the calcium salts. There is evidence of increased salivary calcium in individuals suffering from excessive tartar deposition.

So-called salivary calculi may form in the gland or in the duct. Their composition is similar to that of tartar. This condition is known as *sialolithiasis*.

**Salivary Amylase.** The principal enzyme of the saliva is known as salivary amylase. The name ptyalin, formerly used for this enzyme, is

<sup>1</sup> Dam et al.: *Intern. Z. Vitaminforsch.*, **20**, 234 (1948).

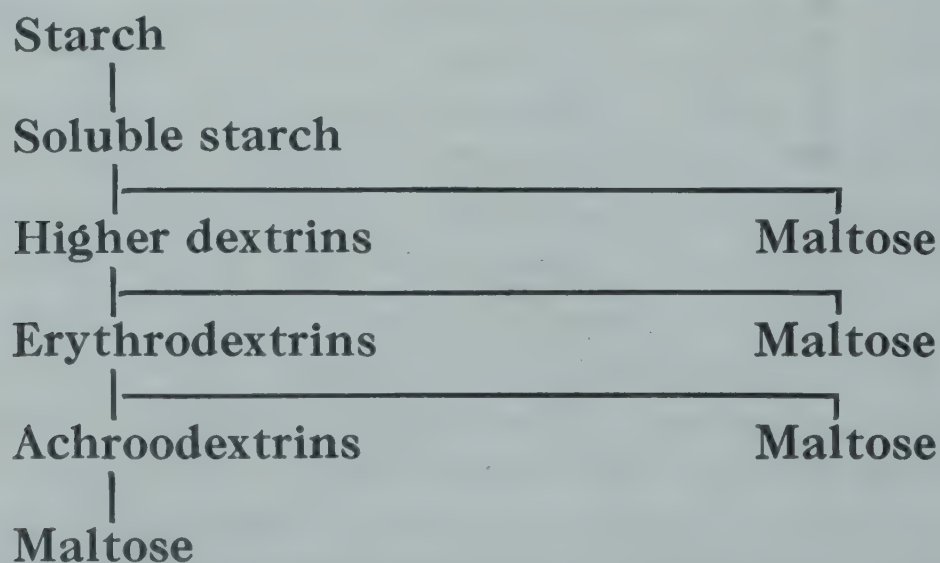

now obsolete. Salivary amylase is an amylolytic enzyme. The enzyme catalyzes the hydrolytic splitting of starch, glycogen, and the dextrans into simpler molecules, the process being a progressive one with the disaccharide maltose as the ultimate end product.

The opinion has been confirmed that the salivary amylase activity varies with the composition of the diet and is highest on a diet which is predominantly carbohydrate.<sup>2</sup>

The first product of the action of the amylase on starch is soluble starch, whose formation is indicated by the disappearance of the opalescence of the starch solution. Soluble starch gives a blue color with iodine; its formation from starch is not associated with the production of free reducing sugar (maltose). Further action of amylase on starch apparently consists largely in the hydrolytic splitting of the second glycoside linkage from a free end of the long chain (straight or branched) of glucose residues which make up the starch molecule. This action produces the disaccharide maltose and a series of smaller polysaccharide molecules which are relatively ill-defined and which are known as the dextrans.

The various dextrans differ in molecular size and complexity, depending upon the extent of amylase action. The higher members of the series resemble starch in giving a blue or purple color with iodine; as the molecule becomes smaller by the splitting off of maltose, a red color is given with iodine (*erythrodextrans*), and the lower members of the series give no color at all with iodine (*achroodextrans*). Thus during the action of salivary  $\alpha$ -amylase on starch, free maltose is produced almost immediately and progressively increases in amount; at the same time the color reaction with iodine changes from blue through red to colorless. Both the increase in reducing sugar and the change in the iodine color reaction are used in following the course of action of amylase on starch. The changes described above may be represented as follows:

These steps in the breakdown of straight and branched glucose chains in amylose and amylopectin are illustrated in Figs. 83 and 84 respectively.

It must be borne in mind, however, that our knowledge of the course of starch hydrolysis by amylase is incomplete. This is due to the complicated nature of both starch (see Chapter 2) and amylase. Most amylases appear to be mixtures of two enzymes,  $\alpha$ - and  $\beta$ -amylase, which are said to

<sup>2</sup> Squires: *J. Physiol.*, **119**, 153 (1953).

produce respectively  $\alpha$ - and  $\beta$ -maltooses on starch hydrolysis. According to one study on malt amylase, starch is completely hydrolyzed to maltose by  $\alpha$ - +  $\beta$ -amylase + a complement present with these in malt. Without the complement, 80 per cent of the starch may be split, leaving 20 per cent of residual dextrin with slight reducing power.  $\alpha$ -Amylase alone leaves about 60 per cent of dextrans giving no color with iodine, while  $\beta$ -amylase alone leaves about 40 per cent of dextrans giving a blue color with iodine. The amylase of saliva is chiefly  $\alpha$ -amylase. Both amylases are found in malt extract. Malt extract kept for several days at 0° C. and at pH 3.6 contains only  $\beta$ -amylase.  $\alpha$ -Amylase is obtained by extraction of ungerminated barley with water.

Salivary amylase acts in alkaline, neutral, or faintly acid solutions. The optimum acidity is pH 6.6. Amylase is destroyed at acidities greater than

FIG. 83. ACTION OF  $\alpha$ -AMYLASE ON AMYLOSE: (O) GLUCOSE UNIT; (-O-O-)  $\alpha$ -1,4-GLUCOSIDIC LINKAGE; (↓)  $\alpha$ -AMYLASE ACTION.

P. Bernfeld: *Adv. Enzymol.*, **12**, 379 (1951).

pH 4 or at concentrations of free HCl greater than 0.0005 per cent. By sufficiently increasing the alkalinity of the saliva, the action of the salivary amylase is inhibited. Salivary amylase has been crystallized.<sup>3</sup>

Electrolytes have an important influence upon the action of amylases. For example, Rockwood has shown that Cl, Br, and NO<sub>3</sub> ions have a pronounced stimulating action upon salivary amylase. Removal of chlorides from saliva by dialysis renders the amylase inactive. Amino acids, particularly asparagine, have an accelerating action. Salts of the heavy metals such as silver and mercury inhibit because they combine with the enzyme, which is apparently of a protein nature.

Because of its sensitivity to acid, salivary amylase ceases to act in the stomach as soon as the gastric contents show throughout the presence of free hydrochloric acid. Since, however, the amylolytic activity of human saliva is very great, an appreciable digestion of starch may occur during the period of mastication and swallowing. Furthermore, the food which is swallowed is not immediately mixed in its entirety with gastric juice and the protein of the food has a certain binding power for free acid, so that a certain interval may intervene between the entrance of the food into the stomach and the destruction of the amylase. This period varies much in different animals and depends also on the size and charac-

<sup>3</sup> Meyer, et al.: *Helv. chim. Acta*, **31**, 2158 (1948).

ter of the meal. In certain experiments on normal men Bergeim found that salivary digestion might continue for 15 to 30 minutes, and that in meals with bread and mashed potatoes there was a conversion of the starch to maltose of about 60 and 75 per cent, respectively.

The digestion of the starch of foods decreases their bulk, and for this reason, and because starch has some inhibitory action on pepsin, salivary

FIG. 84. ACTION OF  $\alpha$ -AMYLASE ON AMYLOPECTIN.

P. Bernfeld: *Adv. Enzymol.*, 12, 379 (1951).

digestion may have some favorable effect on protein digestion in the stomach. The action of salivary amylase is not, however, essential, since the pancreatic juice contains a powerful amylase.

The saliva of rodents is amylolytic. Hog saliva contains amylase, but much less than human saliva. The saliva of carnivorous animals is free from amylase, as is also that of herbivorous animals.

Maltase is found in traces in saliva. Maltase splits maltose into glucose but the amount of such digestion in the mouth is very slight. It is claimed that dipeptide- and tripeptide-splitting enzymes are present in saliva. This action in at least some cases is due to bacteria and in any case is not of digestive importance.

**Mucin.** Mucin gives saliva its viscosity. It is a glycoprotein, insoluble in water or dilute acid but soluble in dilute alkali. When precipitated, as upon the teeth, mucin forms with alkali a slippery mass which dissolves but slowly. It is therefore removed from the teeth with difficulty and may furnish a nucleus for the deposit of other substances. Mucin may be precipitated from saliva by dilute acid or by alcohol. It is an acid substance existing in saliva as the potassium salt. It gives the usual protein color reactions, but is not coagulated by heat in neutral solutions. It is precipitated by saturating with ammonium sulfate. On hydrolysis it yields besides protein a mucoitin sulfuric acid which on further decomposition gives sulfuric acid, acetic acid, glucuronic acid, and glucosamine.

Microscopical examination of saliva reveals epithelial cells, salivary corpuscles (white blood cells?), mucus, food debris, and numerous microorganisms from the true bacteria, higher bacteria, fungi, and protozoa groups. Pus cells and red blood cells may be evident in pathological conditions of the mouth.

## EXPERIMENTS ON SALIVA

A satisfactory method of obtaining the saliva necessary for the experiments which follow is to chew a small piece of pure paraffin wax, thus stimulating the flow of the secretion, which may be collected in a small beaker. It must be remembered in this connection that paraffin-stimulated saliva is quite different in some respects (e.g., pH) from ordinary saliva. Filtered saliva should be used in every experiment except the microscopical examination and the quantitative determination of amylase activity.

**1. Microscopical Examination.** Examine a drop of unfiltered saliva microscopically, after staining with methylene blue, and compare with Fig. 85.

**2. Reaction.** Test the reaction to litmus or other suitable indicator paper. Estimate the approximate pH of the saliva. Measure 2 ml. of fresh saliva into a small test tube. Add 10 drops of an indicator solution suitable for measuring pH at the estimated pH of the saliva.<sup>4</sup> Compare with 2-ml. portions of pH standard solutions<sup>4</sup> treated with the same amount of indicator in similar tubes. The standards should differ by

FIG. 85. MICROSCOPIC CONSTITUENTS OF SALIVA.

*a* Epithelial cells, *b* salivary corpuscles, *c* fat drops, *d* leukocytes, *e*, *f*, *g* bacteria, *h*, *i*, *k* fission-fungi.

<sup>4</sup> See Chapter 1 for the preparation and use of indicators, standards, and the comparator block.

0.2 pH unit.<sup>5</sup> Determine the pH of the saliva. The comparison is best made in a comparator block, with a tube containing saliva only placed behind the standard, and a tube of plain water behind the saliva-indicator tube.

3. *Test for Mucin.* To a small amount of saliva in a test tube add 1 to 2 drops of dilute acetic acid. Mucin is precipitated.

4. *Biuret Test.* Render a little saliva alkaline with an equal volume of NaOH and add a few drops of a very dilute (2 to 5 drops in a test tube of water) copper sulfate solution. The formation of a purplish-violet color is due to mucin. This reaction is given by protein material and simply indicates that mucin is a protein.

5. *Preparation of Mucin.* Pour 25 ml. of saliva into 100 ml. of 95 per cent alcohol, stirring constantly. Cover the vessel and allow the precipitate to stand at least 12 hours. Pour off the supernatant liquid, collect the precipitate on a filter, and wash it, in turn, with alcohol and ether. Finally dry the precipitate, remove it from the paper, and make the following tests on the mucin: (a) Test its solubility in water, dilute acid, and dilute alkali; (b) Millon's reaction; (c) dissolve a small amount in NaOH, and try the biuret test on the solution; (d) boil the remainder, with 10 to 25 ml. of water to which 5 ml. of dilute HCl has been added, until the solution becomes brownish. Cool, render alkaline with solid sodium carbonate, and test by Benedict's solution. Reduction should take place. Why? Does the unhydrolyzed mucin reduce Benedict's solution?

Mucin may also be prepared from salivary glands.

6. *Viscosity Test.* Place filter papers in two funnels, and to each add an equal quantity of starch paste (5 ml.). Add a few drops of saliva to one lot of paste and an equivalent amount of water to the other. Note the progress of filtration in each case. Why does one solution filter more rapidly than the other?

7. *Test for Nitrites.* Add 1 to 2 drops of dilute  $\text{H}_2\text{SO}_4$  to a little saliva and stir thoroughly. Now add a few drops of a freshly prepared potassium iodide solution and some starch paste. Nitrous acid is formed which liberates iodine, causing the formation of a blue color with the starch.

8. *Thiocyanate Test: Solera's Reaction.* This test depends upon the liberation of iodine through the action of thiocyanate upon iodic acid. Moisten a strip of starch paste-iodic acid test paper<sup>6</sup> with a little saliva. If thiocyanate is present the test paper will assume a blue color, owing to the liberation of iodine and the subsequent formation of the so-called iodide of starch.

9. *Digestion of Starch Paste.* To 25 ml. of starch paste in a small beaker, add 5 drops of saliva and stir thoroughly. At intervals of a minute remove a drop of the solution to one of the depressions in a test tablet and test by the iodine test. At the same time add 3 drops of the mixture to one of a series of test tubes set up with 5-ml. portions of Benedict's reagent. The opalescence of the starch solution should soon disappear, indicating the formation of

<sup>5</sup> To obtain a closer approximation of the reaction of saliva in the mouth, draw the sample into a pipet directly from the mouth (without previous chewing of paraffin), and dilute with the indicator in the test tube, under a thick layer of mineral oil. (Krasnow, Oblatt, and Kaplan: *J. Dental Research*, 15, 367 (1936).)

<sup>6</sup> See Appendix.

soluble starch which gives a blue color with iodine. The soluble starch should soon be transformed into erythrodextrin which gives a red color with iodine, and this in turn should pass into achroodextrin which gives no color with iodine. This is called the achromic point. When this point is reached, complete the Benedict tests by placing all the tubes in a boiling water bath for 3 minutes, and note the degree of reduction in each tube. Tabulate your results with the iodine and Benedict tests in parallel columns. Also perform a phenylhydrazine test for maltose (the osazone crystals may not have the typical appearance of maltosazone). A positive Benedict test may be obtained while the solution still reacts red with iodine, inasmuch as some maltose is formed from the soluble starch coincidentally with the formation of the erythrodextrin. How long did it take for a complete transformation of the starch? Saliva from different individuals may vary markedly in amylolytic power. For a graphic representation of the above changes see p. 352.

**10. Separation of the Products of Salivary Digestion.** To 25 ml. of 1 per cent starch paste in a small beaker add 1 ml. of saliva and stir thoroughly. At intervals of one minute test a drop of the mixture by the iodine test. If the blue color persists after five minutes add another 1 ml. of saliva. When the mixture reacts red with iodine, indicating that erythrodextrin has been formed, add 100 ml. of 95 per cent alcohol. Allow to stand until the white precipitate has settled. Filter, evaporate the filtrate to dryness on a water bath, dissolve the residue in 5 to 10 ml. of water, and try Benedict's test and the phenylhydrazine reaction. On the dextrin precipitate try the iodine test.

**11. Influence of Temperature.** Into each of four tubes place about 5 ml. of 0.2 per cent starch paste. Immerse one tube in a beaker containing crushed ice, keep a second at room temperature, and place a third in the incubator or the water bath at 40° C. (If the temperature of the bath or incubator is allowed to rise to 70° C. or over the enzyme is destroyed and no digestion takes place.) Now add to the contents of each of these three tubes 5 drops of saliva and shake well; to the contents of the fourth tube add 5 drops of boiled saliva. Test frequently by the iodine test, using the test tablet, and note in which tube the most rapid digestion occurs. Explain the results.

**12. Estimation of Amylase in Saliva.** Pipet exactly 1 ml. of unfiltered saliva into a 100-ml. cylinder. Dilute to the 100-ml. mark, and mix well. Pipet 5 ml. of 1 per cent soluble starch into a test tube. Add 2 ml. of 1 per cent NaCl solution and 2 ml. of a buffer solution of pH 6.6<sup>7</sup> and put in a water bath maintained at 38° C. Prepare a series of 10 test tubes, each containing 2 ml. of a light yellow iodine solution. Now add 1 ml. of diluted saliva to the starch mixture and return to the bath at once. Record the time of this addition. At the end of each minute of digestion, with a pipet remove 2 drops of the mixture and add to one of the tubes of iodine solution. Record the time when no change in color appears in the iodine solution (achromic point). If this time is less than 5 or more than 20 minutes, repeat, using a different dilution of saliva such as will give a digestion time of about 10 minutes. Thus if 3 minutes are required, dilute 30 ml. of the original diluted saliva to 100 ml., and use 1 ml. of this for the test.

One unit of amylase may be considered to be the amount required to digest 5 ml. of 1 per cent soluble starch to the achromic point in 10 minutes under the conditions of the test. The number of units of amylase in 1 ml. of the saliva tested will equal 100 (or whatever the dilution of the original saliva might be)  $\times 10 \div$  the number of minutes to the achromic point. From 100 to 150 units are frequently found.

13. *Influence of NaCl on Salivary Amylase.* Repeat the preceding experiment but replace the NaCl solution by water. A longer time should be required, showing that NaCl accelerates the action of salivary amylase. If saliva be dialyzed free from chlorides it becomes inactive.

14. *Influence of pH on Salivary Amylase.* In Exp. 12 the solution had a pH of 6.6. Replace the phosphate buffer of this experiment by another buffer of pH 5.8 and in a second experiment use a buffer of pH 8.0.<sup>7</sup> Which gives digestion in the shortest time and is hence nearest the optimum pH?

15. *Excretion of Potassium Iodide.* With the aid of a glass of water, ingest a small dose of potassium iodide (0.2 g.) contained in a gelatin capsule, quickly rinse out the mouth with water, and then test the saliva at once for iodine. This test should be negative. Make additional tests for iodine at two-minute intervals. The test for iodine is made as follows: Take 1 ml. of dilute NaNO<sub>2</sub> solution and 1 ml. of dilute H<sub>2</sub>SO<sub>4</sub><sup>8</sup> in a test tube; add a little saliva directly from the mouth, and a small amount of starch paste. The formation of a blue color signifies that the potassium iodide is being excreted through the salivary glands. Note the length of time elapsing between the ingestion of the potassium iodide and the appearance of the first traces of the substance in the saliva. If convenient, the urine may also be tested at 15- or 30-minute intervals after ingestion of the iodide. The chemical reactions taking place in this experiment are indicated in the following equations:

Inasmuch as iodide is absorbed from the stomach very slowly, if at all, but is very rapidly absorbed when it enters the intestine, the rapidity of appearance of the iodide in the saliva is an index of the rapidity with which the drug leaves the stomach, which depends on the motor activity of the stomach, the amount of food therein, etc. By drinking a glass of water with the iodide a more rapid result is obtained.

## Gastric Digestion

Following mastication the food is carried by peristaltic movements of the esophagus to the stomach. Here it undergoes further mechanical disintegration and chemical changes, primarily in the protein constituents. The food thus treated is in a better condition to be handled by the intestines, to which it is passed on in small portions at a time, and in which digestion is completed.

Spallanzani (1783) found that gastric juice dissolved meat, and so demonstrated the chemical nature of gastric digestion. He noted also that the juice was acid, but the nature of this acid and of the active agent pepsin was not demonstrated until later.

A great advance in our knowledge of gastric digestion, particularly in man, was made through the observations of Beaumont on his patient Alexis St. Martin, who in 1822, following a gunshot wound, was left with an opening from the stomach through the abdominal wall to the exterior. Through this fistula Beaumont found it possible to follow the course of gastric digestion with different foods and under varying conditions of health, and to obtain pure gastric juice for digestion experiments outside the body.

Pavlov extended our knowledge, particularly through the development of an operation by means of which he created in dogs a small stomach pouch separate from the main stomach, and opening to the exterior, so that the secretion in the small pouch could be studied without interfering with processes in the stomach proper. In this way the influence of different foods and of other factors on gastric secretion could be studied. The development of the small stomach tube which could be retained in place throughout the period of gastric digestion and allowed aspiration of the stomach contents at any time, has given additional information of physiological and clinical value.

**Secretion of Gastric Juice.** There is a slight continuous secretion of gastric juice into the empty stomach. As a result there is almost always present in the stomach before meals about 50 ml. of secretion which is called the residuum. Gastric secretion is governed by many factors. At least three phases are recognized.

(1) **PSYCHIC PHASE.** Following the presentation of food and before any food reaches the stomach, there is a psychic secretion of gastric juice. This is induced by the sight, taste, smell or thought of food. Ivy has called this the "cephalic phase."

(2) **GASTRIC PHASE.** Following this, with the passage of food into the stomach, there occurs the gastric phase of gastric secretion due to the

local chemical action of such substances as protein digestion products, or meat extractives, and some mechanical action due to friction and distention of the stomach by food. A substance, *gastrin*, has been isolated from gastric mucosa (Edkins). When injected into the blood, this markedly stimulates gastric secretion. It is believed to be a hormone of gastric secretion, i.e., a substance liberated from the gastric mucosa in the presence of food and passing by way of the blood to the acid-secreting cells, stimulating them to action. *Histamine*, the decarboxylation product of the amino acid histidine is also a powerful stimulant of gastric secretion in addition to its well-known effect on blood pressure (capillary dilatation). The question whether or not gastrin is identical with histamine was unanswered for some years. They are now believed to be separate substances which possess similar action.<sup>1</sup> The chemical structure of histamine is shown on p. 1037. The structure of gastrin is not known. Clinical use is made of the secretagogue effect of histamine, alcohol, and caffeine.

(3) **INTESTINAL PHASE.** A third, intestinal phase of gastric secretion is brought about through the action of protein digestion products and other food substances in the intestines. Whether these substances act by liberating a hormone from the mucosa, or are absorbed and themselves act upon the gastric cells is not yet clear. Undigested fat in the intestine inhibits gastric secretion, apparently by liberating from the mucosa a hormone called enterogastrone which depresses the action of the gastric cells. This *chalone* also inhibits gastric movements and was for a time considered useful in the treatment of gastric ulcer. However, evidence of its ineffectiveness has accumulated. For example, Wollum and Pollard<sup>2</sup> found no significant alteration in the secretory or motor patterns from its use, and Bone<sup>3</sup> has reported that it has little or no value. Clinical research has indicated that the chemical substances called *Banthine*, *Pro-banthine*, and *Prantal* are useful in the treatment of ulcer (see p. 383). Urogastrone, a substance similar in action to enterogastrone and found in the urine, is apparently a metabolic derivative of enterogastrone.

Water has a stimulating action on gastric secretion, and the drinking of considerable water has been shown to improve the utilization of various foods. Nor has the drinking of water with meals by normal individuals been shown to be undesirable.<sup>4</sup> The influence of different foods on gastric secretion is discussed later.

The study of gastric secretion and the gastric mucosa in nutritional deficiencies has received some attention. Thus in canine blacktongue (the closest animal counterpart to human pellagra), a mild pallor of the gastric mucosa was observed consistently upon gastroscopic examination.<sup>5</sup> This was accompanied by anemia, loss of weight, and decreased muscular tone of the stomach wall. The tonus of the stomach returned to normal as early as six to seven days after the institution of therapy. There was no

<sup>5</sup> Layne and Carey: *Gastroenterology*, **2**, 133 (1944).

change in acid gastric secretion during the disease or following niacin therapy. The therapeutic effect of thiamine was also negative. Shapiro and his co-workers<sup>6</sup> found atrophic gastritis to be somewhat more common in nutritional deficiencies, than in a control group of ten other patients. However, no significant changes in the gastric mucosa were observed after treatment with large doses of thiamine, niacin, riboflavin, pantothenic acid, *p*-aminobenzoic acid, and vitamin A. In two cases the atrophic changes disappeared after choline chloride therapy.

**Composition of Gastric Juice.** Normal gastric juice is a thin, light-colored fluid which is acid in reaction and has a specific gravity averaging about 1.007. It contains about 0.5 per cent of solid matter which is made up principally of sodium chloride, potassium chloride, earthy phosphates, mucin, and the enzymes pepsin and gastric lipase. The acidity of the gastric juice is due to *free* hydrochloric acid. The gastric juice is a composite secretion from at least three different types of cells in the gastric mucosa; these are (1) the parietal cells, (2) the chief cells, and (3) the mucous cells. There is good evidence that the parietal cells furnish the hydrochloric acid of gastric juice, the chief cells supply pepsin and possibly other enzymes, and the mucous cells secrete mucin. Babkin<sup>7</sup> claims that the secretory activity of the various types of gland cells should not be considered en masse but rather that "various nerves . . . or chemical agents stimulate or inhibit each set of secretory elements separately." This view is also accepted by others.<sup>8</sup>

*Apoerythein*, a protein fraction, also occurs in gastric juice.<sup>9</sup> It has been suggested that this substance may be identical with the *intrinsic factor of Castle*, which protects vitamin B<sub>12</sub> (the extrinsic factor) from digestive destruction. Pernicious anemia is characterized by a deficiency of the intrinsic factor. Vitamin B<sub>12</sub> is relatively ineffective when given orally to such patients, but is highly effective when administered parenterally.

It is believed that the parietal-cell secretion is essentially an isotonic solution consisting largely of hydrochloric acid (about 160 milliequivalents per liter) and potassium chloride (about 7 milliequivalents per liter). The acidity of the parietal-cell secretion corresponds therefore to a solution 0.16 N in hydrochloric acid, or containing 0.5 to 0.6 per cent hydrochloric acid. This maximal acidity, which is apparently constant and independent of the rate of secretion, is lowered somewhat as soon as the parietal-cell secretion becomes admixed with the slightly alkaline secretions from the chief cells and mucous cells. These latter secretions contain a high concentration of neutral chlorides as a result of which the acidity is reduced to a greater extent than is total chloride content. The acidity may also be lowered by regurgitation of alkaline fluid from the intestine and by ingested food; so that the actual acidity of gastric juice as collected usually varies between 0.05 and 0.1 N (0.18 to 0.36 per cent hydrochloric acid). The acidity of the gastric juice is usually expressed in terms of the number of milliliters of 0.1 N sodium hydroxide required to

<sup>6</sup> Shapiro *et al.*: *ibid.*, 2, 121 (1944).

neutralize 100 ml. of gastric juice; this is obviously equivalent to the number of milliliters of 0.1 N hydrochloric acid present in 100 ml. of gastric juice, which corresponds numerically with the concentration of acid expressed in terms of milliequivalents per liter. In clinical practice this value is sometimes called the degree of acidity; thus a gastric juice containing 60 milliequivalents of acid per liter, or requiring 60 ml. of 0.1 N alkali to neutralize 100 ml., is said to have an acidity of 60 degrees.

The hydrochloric acid of the gastric juice forms a medium in which the pepsin can most satisfactorily digest the protein food, and at the same time it acts to some extent as an antiseptic or germicide which prevents putrefactive processes in the stomach. When the hydrochloric acid of the gastric juice is diminished in quantity (hypoacidity) or absent, as it may be in many cases of functional or organic disease, there is no check to the growth of microorganisms in the stomach. There are, however, certain of the more resistant spores which even the normal acidity of the gastric juice will not destroy. A condition of hypoacidity may also give rise to fermentation with the formation of comparatively large amounts of such substances as lactic acid and butyric acid.

When free hydrochloric acid comes in contact with protein, as in the food, a reaction occurs with the formation of protein hydrochloride. This was formerly called "combined hydrochloric acid," but this term is so indefinite in its connotation that it should be abandoned (see p. 380). The formation of protein hydrochloride considerably raises the pH of gastric contents, since protein hydrochloride is a much less highly ionized acid than is hydrochloric acid itself. The reduction in hydrogen-ion concentration resulting from the formation of protein hydrochloride may permit processes which are acid-sensitive to proceed during gastric digestion, such as bacterial action or the action of salivary amylase (see p. 353).

**Origin of Gastric Acid.** The mechanism whereby the stomach produces a secretion which is about three million times more acid than the blood is not known. Many attempts have been made to solve this problem, and various theories have been proposed, none of which has received universal acceptance.

The currently favored view for the formation of acid by the parietal cells is based upon the discovery by Davenport<sup>10</sup> that the enzyme carbonic anhydrase (see Chapter 24) is present in large amounts in the parietal cells, and is relatively absent from the other cells of the gastric mucosa. This enzyme also occurs in red blood cells. It has been crystallized and found to contain 0.2 per cent zinc.<sup>11</sup> Potent inhibitors of carbonic anhydrase (like certain sulfa drugs) also depress hydrochloric acid secretion in the living animal.<sup>12</sup> Carbonic anhydrase catalyzes the hydration of carbon dioxide to carbonic acid, which dissociates in solution to yield hydrogen ions and bicarbonate ions:

<sup>10</sup> See Davenport: *Gastroenterology*, **1**, 383 (1943); Gray: *ibid.*, **1**, 390 (1943).

<sup>11</sup> Sumner and Somers: *Chemistry and Methods of Enzymes*, 3rd ed. New York, Academic Press Inc., 1953.

<sup>12</sup> Janowitz, Colcher, and Hollander: *Trans. N.Y. Acad. Sci.*, **15**, 54 (1952).

If this reaction is pictured as occurring within the parietal cell, the carbon dioxide coming from metabolic processes, the hydrogen ions may be visualized as being secreted, along with an equivalent number of chloride ions, into the stomach while the bicarbonate ions enter the blood.

Here bicarbonate ion replaces chloride ion, which diffuses into the parietal cell and is available for excretion along with hydrogen ions into the gastric juice. Thus according to this theory the hydrogen ions of the gastric juice come from carbonic acid, and the chloride ions are derived from the blood. The replacement of blood chloride by bicarbonate should raise the pH of the blood, and in fact it has been shown that blood leaving the stomach during active gastric secretion is significantly more alkaline than the entering blood thus accounting for the "alkaline tide" (see p. 784).

It is an interesting consequence of this theory that the extra bicarbonate of gastric venous plasma as compared to gastric arterial plasma is the result of the direct entrance of bicarbonate as such into the plasma, and not the result of the entrance of anhydrous carbon dioxide into the blood followed by its hydration to carbonic acid in the red cell and diffusion from the red cell into the plasma; processes which are known to account for the extra bicarbonate of venous plasma over arterial plasma in other parts of the body. Now in ordinary venous plasma the increase in plasma bicarbonate due to diffusion of bicarbonate from the red cell into the plasma is associated with a chloride shift (see Chapter 24), chloride ions leaving the plasma and entering the red cell. In gastric venous plasma the increased plasma bicarbonate brings about a reversed chloride shift by diffusion into the red cell at the expense of chloride ions which diffuse out into the plasma. This has been cited as further evidence concerning the role of carbonic anhydrase in the formation of gastric acid. It should be remembered, however, that though this theory accounts for the production of acid by the parietal cell, no direct evidence concerning the actual mechanisms of formation and secretion is as yet available, and other theories<sup>13</sup> are not as yet untenable.

**Pepsin.** The most characteristic of the enzymes of the gastric juice is the proteolytic enzyme pepsin. Pepsin is a representative of a large group of enzymes, many of which are found in the gastrointestinal tract and all of which catalyze the hydrolytic splitting of the peptide bond,  $\text{—CO—NH—}$  to produce a free amino and a free carboxyl group. Within this group of peptide-splitting enzymes, two general types may be distinguished (Bergmann): (1) the proteinases or endopeptidases, and (2) the peptidases or exopeptidases. The endopeptidases act upon peptide linkages in both the central portion and the terminal portion of a polypeptide chain; the exopeptidases split peptide linkages in the terminal portion of the chain only. Differences between the various endo- and exopeptidases of the gastrointestinal tract are attributed largely to differences in the type and location of the amino acids united in the peptide bond, as will be evident in this and subsequent chapters. According to this classification, pepsin is an endopeptidase, since it can act upon peptide linkages

within the large protein or polypeptide molecule as well as upon synthetic peptides (see below).

Pepsin is apparently formed by the action of the hydrogen ions of the gastric juice on a precursor or zymogen, called *pepsinogen*, originating in the chief cells of the gastric mucosa. Both pepsin and pepsinogen are proteins and have been prepared in crystalline form;<sup>14</sup> crystalline pepsin appears, however, to be a mixture of enzymes rather than a single substance. Pepsinogen is more resistant to alkali than is pepsin. It does not clot milk at pH 5 nor liquefy gelatin at pH 4.7, but pepsin is active under these conditions. The formation of pepsin at pH 4.6 appears to be an autocatalytic reaction; i.e., the pepsin as it is formed acts upon further pepsinogen to yield still more pepsin. Since pepsin is known to act only on peptide linkages with a specific amino acid configuration (see below), it would appear that the activation of pepsinogen may involve the breaking of such linkages. The isoelectric point of pepsin is at such a low pH that it has not been accurately established.

Pepsin contains phosphorus. It is denatured and coagulated by heat, with the loss of peptic activity running parallel with the degree of denaturation. It is also inactivated and denatured in alkaline solutions (pH 10). In such cases there is some return of activity on acidification and standing; thus there has been a reversal of the denaturation of the pepsin protein. Pepsin is digested by trypsin in solutions more alkaline than pH 5.5. In more acid solutions trypsin is digested by pepsin. It has been shown that when pepsin is mixed with egg albumin in the pH range 3.1 to 4.2 a precipitate is formed which is not denatured protein.<sup>15</sup>

Pepsin acts very well at 40° C. The optimum pH is about 2.0, but this has been shown to be more related to the ionization of the substrate protein than to any effect on the enzyme itself. A variety of mineral and organic acids may be used to attain this pH with practically identical effects on the enzyme activity. At pH 4 its activity is very slight and at pH 5 it is stable but inactive. At pH values of 6.0 or greater it is unstable, and above pH 8 it is rapidly destroyed by OH ions.

**Products of Peptic Hydrolysis.** The gastric acid acting on food proteins at body temperature produces denatured proteins ("acid metaprotein"). Pepsin acts upon such denatured protein as well as upon native protein with the formation largely of protein derivatives of relatively low molecular weight (not over 1,000, according to Tiselius and Eriksson-Quensel<sup>16</sup>); such split products belong to the ill-defined class of the proteoses and peptones. In the normal time of gastric digestion, substances of this nature appear to be the chief end products of peptic action. Free tyrosine is also a frequent product of peptic digestion. The nature of the action of pepsin has been considerably clarified by the work of Bergmann, Fruton, and associates. They have studied the action of crystalline pepsin

---

<sup>14</sup> For discussion of crystalline pepsin see pp. 305 and 330. For preparation of crystalline pepsinogen see Herriott and Northrop: *Science*, **83**, 469 (1936); and Herriott: *J. Gen. Physiol.*, **21**, 501 (1938).

on synthetic substrate peptides of known chemical constitution. All synthetic substrates which were hydrolyzable by pepsin contained either tyrosine or phenylalanine in the molecule, with the peptide linkage specifically involving the *amino* group of these amino acids. If the tyrosine or phenylalanine was at the end of the peptide chain, hydrolysis proceeded more rapidly and the free amino acid was liberated, but peptic action was not limited to the presence of the amino acid at the end of a chain. Thus one may conclude that pepsin acts on peptide linkages associated with the presence of tyrosine or phenylalanine (although the possibility of other amino acids being concerned in peptic action is not necessarily excluded); the end product of the action will depend upon the relative position of these amino acids in the long chain of amino acid residues in the protein substrate. Pepsin acts upon practically all native proteins with the exception of keratin and the protamines; its lack of action in the case of keratins is believed to be due to the close packing of the polypeptide chains in the keratin molecule; in the case of protamines, to their deficiency in tyrosine and phenylalanine.

In testing peptic activity at pH from 1 to 2.85 Currie and Bull<sup>17</sup> report that pepsin acts as a proteinase at the lower pH and splits fewer peptide linkages per mole of substrate thus yielding fragments of relatively high molecular weight. On the other hand, at a higher pH it acts as a peptidase and yields fragments of smaller molecular weight. As to the influence of temperature it was found that at 30° C. or below the digestion products possessed relatively low molecular weights whereas at temperatures between 35° C. and 50° C. the products of hydrolysis were of high molecular weight. The conclusion can therefore be drawn from these experiments that pepsin acts very efficiently at pH 2.85 and at about 30° C.

**Rennin.** Rennin is what is known as a milk-curdling or protein-coagulating enzyme. It is a proteinase which, acting upon the casein of milk, is believed to form first a soluble paracasein and a peptone-like body. In the presence of ionized calcium salts there is then formed an insoluble calcium paracaseinate which separates out as a curd. Rennin is commonly obtained from the mucosa of the fourth stomach of the calf and is used to curdle milk in cheese-making.

The matter was the subject of a long controversy, but it appears now to be clear that the enzyme, rennin, is an entity quite distinct from pepsin. It has very high milk-curdling power but practically no protein-digesting activity. In certain animals the curdling of milk is caused by pepsin. Pepsin can coagulate milk in practically neutral solution as contrasted with the high acidity required for its action on proteins in general.

Rennin acts best at a pH of 6.0 to 6.5 and at a temperature of about 45° C. Tauber and Kleiner have obtained a preparation curdling 4,550,000 times its weight of milk at pH 6.2 in 10 minutes at 40° C. The preparation has an isoelectric point of 5.4. It is apparently a diffusible proteose containing sulfur and is not coagulated by heat. It does not give the Millon and Hopkins-Cole tests. Rennin appears to exist in the calf's mucosa as prorennin, which is activated by the gastric acidity.

**The Action of Gastric Juice on Milk.** A comparison between the large tough curds formed in the stomach from cow's milk and the small soft curds formed from human milk is shown in Figures 86 to 89, below.<sup>18</sup>

**Gastric Lipase.** A third enzyme present in gastric juice is a fat-splitting enzyme. It possesses but slight activity when the gastric juice is of

normal acidity, but evinces its action principally at such times as a gastric juice of low acidity is secreted either from physiological or pathological cause. It thus may be of importance in the young animal where gastric acidity is considerably lower than in the adult. The digestion of fat in the stomach is, however, at most of but slight importance as compared with the digestion of fat in the intestine through the action of the

<sup>18</sup> Bergeim, Evvard, Rehfuss, and Hawk: *Am. J. Physiol.*, 48, 411 (1919).

lipase of the pancreatic juice (see p. 397). The presence of lipase in the gastric lumen, like that of trypsin, is probably due to regurgitation of intestinal contents through the pylorus.

NORMAL GASTRIC RESPONSE TO COMMON FOODS

On the basis of extensive studies made in the senior author's laboratory<sup>19</sup> the following table was constructed which contains data relative

EVACUATION TIMES AND HIGHEST TOTAL ACIDITIES FOR VARIOUS ARTICLES OF DIET

protein, and for which gastric digestion is hence of the greatest importance, remain longest in the stomach (3 to 4 hours) and give rise to the highest acidities (120 or higher). Foods low in protein, such as fruits and many vegetables, leave the stomach soon (1.5 to 2 hours) and give rise to much less secretion. Foods intermediate in protein content, such as cereal foods, show intermediate acidities and emptying times. Milk has considerable buffer action. Water leaves the stomach rapidly.

The relationship of the average evacuation times of the various foods

is shown graphically in Fig. 90, whereas the variation in the evacuation time of the same food by fast and slow stomachs is shown in Fig. 91.

## COLLECTION OF HUMAN GASTRIC JUICE

Have one or more volunteers from the class take the Rehfuß stomach tube as directed on p. 384. The subjects must omit breakfast if the tube is taken in the morning, or luncheon if taken in the afternoon. Empty the stomach (see pp. 384–385) and, with the tube still in place, allow each subject to drink 250 ml. of water. The water will stimulate the flow of gastric juice and will itself quickly leave the stomach. In many instances fairly concentrated gastric juice may be obtained from the stomach in from 30 to 45 minutes after the introduction of the water. Remove this gastric juice according to procedure outlined on p. 386. For the composition of human gastric juice see p. 377. See also Exp. 9, p. 373. If thought desirable, the gastric juice resulting from psychical stimulation (see p. 373) or following histamine injection (see p. 385) may be collected instead of that following the chemical stimulation of water. (Curves showing the stimulatory power of water are given in Fig. 92.)

## PREPARATION OF ARTIFICIAL GASTRIC JUICE

**1. From Pig's Stomach.** Dissect the mucous membrane of a pig's stomach from the muscular portion and discard the latter. Divide the mucous membrane into two parts (four-fifths and one-fifth). Cut up the larger portion, place it in a large-sized beaker with at least 4 volumes of 0.4 per cent hydrochloric acid, and keep at 38° to 40° C. for at least 24 hours. Add more HCl as needed to keep the mixture acid to Congo red paper; otherwise putrefaction may occur. Filter off the residue, consisting of nuclein and other substances, and use the filtrate as an artificial gastric juice. This filtrate contains pepsin and the products of the digestion of the stomach tissues; i.e., denatured protein, proteoses, and peptones.

**2. From Commercial Pepsin.** Dissolve 750 mg. of U.S.P. pepsin in 100 ml. of 0.1 N hydrochloric acid.

## PREPARATION OF A GLYCEROL EXTRACT OF PIG'S STOMACH

Take the one-fifth portion of the mucous membrane of the pig's stomach not used in the preparation of the artificial gastric juice, cut it up finely, place it in a small-sized beaker, and cover the membrane with glycerol. Stir frequently and allow to stand at room temperature for at least 24 hours. The glycerol will extract the pepsinogen. With a pipet or by other means, sepa-

FIG. 92. CURVES SHOWING STIMULATORY POWER OF WATER.

Bergeim, Rehfuß, and Hawk: *J. Biol. Chem.*, 19, 345 (1914).

rate the glycerol from the pieces of mucous membrane and use the glycerol extract as required in the later experiments.

## PRODUCTS OF GASTRIC DIGESTION

Into the artificial gastric juice, prepared as above described, place the protein material (fibrin, coagulated egg white, or lean beef) provided for you by the instructor, add 0.4 per cent hydrochloric acid as suggested by the instructor, and keep the digestion mixture at 40° C. for two to three days. Stir frequently and keep free hydrochloric acid present in the solution as indicated by a blue color with Congo red paper.

The original protein has been digested and the solution now contains the products of peptic proteolysis; i.e., denatured protein, proteoses, peptones, etc. The insoluble residue may include nuclein and other substances. Filter the digestion mixture, and after testing for free hydrochloric acid neutralize the filtrate with sodium hydroxide solution. If any of the denatured protein is still untransformed into proteoses, it will precipitate upon neutralization. If any precipitate forms, heat the mixture to boiling and filter. If no precipitate forms, proceed without filtering.

We now have a solution containing a mixture consisting principally of proteoses and peptones. Separate and identify the proteoses and peptones according to the directions given on p. 197.

## GENERAL EXPERIMENTS ON GASTRIC DIGESTION

**1. Conditions Essential for the Action of Pepsin.** Prepare four test tubes as follows:

- (a) Five ml. of pepsin solution.
- (b) Five ml. of 0.4 per cent hydrochloric acid.
- (c) Five ml. of pepsin–hydrochloric acid solution.<sup>20</sup>
- (d) Two or 3 ml. of pepsin solution and 2 to 3 ml. of 0.5 per cent sodium carbonate solution.

Into each tube introduce a small piece of fibrin and place tubes in the incubator or water bath at 40° C. for one-half hour, carefully noting any changes which occur.<sup>21</sup> (Carmine-fibrin<sup>22</sup> may be used to advantage in this and the following tests under Gastric Digestion. In this case, however, the experiments should be conducted at room temperature.) Now combine the contents of tubes (a) and (b) and see if any further change occurs after standing at 40° C. for 15 to 20 minutes. Explain the results obtained from these five experiments.

**2. Influence of Different Temperatures.** In each of five test tubes place 5 ml. of pepsin–hydrochloric acid solution. Immerse one tube in ice water, keep a second tube at room temperature, place a third in the incubator or water bath at 30° C., and keep the fourth at 50° C. Boil the contents of the fifth tube for a few moments; then cool and also keep it at 30° C. Into each tube intro-

<sup>20</sup> 0.75 per cent commercial pepsin in 0.4 per cent HCl may be used.

<sup>21</sup> Digestion of fibrin in a pepsin–hydrochloric acid solution is indicated first by a *swelling* of the protein due to the action of the acid, and later by a *disintegration* and *solution* of the fibrin due to the action of the pepsin–hydrochloric acid. If uncertain at any time whether digestion has taken place, the solution under examination may be filtered and the biuret test applied to the filtrate. A positive reaction will signify the presence of proteoses (albumoses) or peptones, the presence of which would indicate that digestion has taken place. The biuret reaction must be more positive than that given by the pepsin–hydrochloric acid solution alone.

<sup>22</sup> See Appendix.

duce a small piece of fibrin and note the progress of digestion. In which of the tubes does the most rapid digestion occur? Explain this.

3. *The Most Favorable Acidity.* Prepare three tubes as follows:

(a) 3 ml. of pepsin solution + 3 ml. of 0.4 per cent HCl. (Acidity about 0.2 per cent HCl or pH 1.3.)

(b) 3 ml. of pepsin solution + 1 ml. of 0.4 per cent HCl + 2 ml. of water. (Acidity about 0.067 per cent HCl or pH 1.8.)

(c) 3 ml. of pepsin solution + 4 drops or 0.2 ml. of 0.4 per cent HCl + 3 ml. of water. (Acidity about 0.013 per cent HCl or pH 2.5.)

Introduce a small piece of fibrin into each tube, keep them at 40° C., and note the progress of digestion. In which acidity does pepsin act best on fibrin? The acid decreases during digestion due to its combination with protein, so that as a determination of optimum pH this procedure is not exact. The optimum for pepsin is about pH 1.8 under the conditions of this experiment.

4. *Differentiation Between Pepsin and Pepsinogen.* Prepare five tubes as follows:

(a) Few drops of glycerol extract of pepsinogen + 2 to 3 ml. of water.

(b) Few drops of glycerol extract of pepsinogen + 5 ml. of 0.2 per cent hydrochloric acid.

(c) Few drops of glycerol extract of pepsinogen + 5 ml. of 0.5 per cent sodium carbonate.

(d) Two or 3 ml. of pepsin solution + 2 to 3 ml. of 1 per cent sodium carbonate.

(e) Few drops of glycerol extract of pepsinogen + 5 ml. of 1 per cent sodium carbonate.

Add a small piece of fibrin to the contents of each tube, keep the five tubes at 40° C. for one-half hour, and observe any changes which may have occurred. To (a) add an equal volume of 0.4 per cent hydrochloric acid, neutralize (c), (d), and (e) with hydrochloric acid, and add an equal volume of 0.4 per cent hydrochloric acid. Place these tubes at 40° C. again and note any further changes which may occur. What contrast do you find in the results from the last three tubes? On the basis of these tests, what is the relative resistance of pepsin and pepsinogen to alkalies?

5. *Comparative Digestive Power of Pepsin with Different Acids.* Prepare a series of six test tubes each containing 5 ml. of a solution of one of the following acids<sup>23</sup> each solution having the same acidity of pH 2: (1) HCl, (2) H<sub>2</sub>SO<sub>4</sub>, (3) H<sub>3</sub>PO<sub>4</sub>, (4) oxalic acid, (5) lactic acid, (6) acetic acid. Add 2 ml. of 0.5 per cent pepsin solution or 1 ml. of the glycerol extract of the hog's stomach and a small piece of fibrin. Put in a water bath and keep at 40° C. Note the progress of digestion. Can you confirm the findings of other observers<sup>24</sup> that it is the hydrogen-ion concentration (pH), rather than the nature of the acid present, which is the controlling factor in the influence of acids on peptic digestion?

Titrate 10 ml. of each of these acids (lactic and acetic acids only 1 ml.)

<sup>23</sup> HCl 0.037 per cent, H<sub>2</sub>SO<sub>4</sub> 0.059 per cent, H<sub>3</sub>PO<sub>4</sub> 0.2 per cent, oxalic acid crystals 0.15 per cent, lactic acid 7.2 per cent, and acetic acid 18 per cent. These solutions are best checked for pH by adding a few drops of thymol blue solution to 5 ml. of each in test tubes and if necessary adding more acid to get the same color as obtained with the oxalic acid, which can be weighed out accurately.

<sup>24</sup> Northrop (*J. Gen. Physiol.*, 1, 607 (1919); 5, 263 (1922)) finds, however, that acetic acid is slightly less effective than the others apparently because of some action of the acetic acid not on the enzyme but on the protein.

with 0.1 N NaOH, using phenolphthalein as an indicator. Calculate the normality of each. Six students may conveniently work together on this part of the experiment, each student then assembling the entire data. What does this experiment teach as to the relationship of hydrogen-ion concentration to titratable acidity and as to the biological significance of each?

6. *Quantitative Determination of Peptic Activity.* See Chapter 15, Gastric Analysis.

FIG. 93. CURVES SHOWING STIMULATORY POWER OF BEEF EXTRACT.

From unpublished data collected in the senior author's laboratory by Dr. Chester C. Fowler.

7. *Quantitative Determination of Rennin.* Prepare a standard milk of pH 5.0 by mixing equal volumes of fresh milk and M acetate buffer of pH 5.0. Introduce 10-ml. portions of this milk into a series of test tubes and keep at 20° C. Add 1-ml. portions of various dilutions of a rennin solution.<sup>25</sup> Mix and note the time of clotting. The amount of rennin that clots 1 ml. of the buffered milk in 10 minutes at 20° C. is called one unit of rennin.

8. *Characteristics of Human Gastric Juice.* Take some of the human gastric juice collected as described on p. 369 and show that it is acid in reaction, that it contains chlorides, and that it has the power to digest protein material and to curdle milk.

<sup>25</sup> Any good commercial rennet may be used in preparing this solution.

9. *Chemical and Psychical Stimulation of Gastric Secretion.* Have one or more volunteers from the class swallow the Rehfuß stomach tube as directed on p. 384. The subjects must omit breakfast if the tube is taken in the morning or luncheon if taken in the afternoon. Empty the stomach (see pp. 384–385) and, with the tube still in position, allow each subject to drink 250 ml. of

FIG. 94. CURVES SHOWING PSYCHICAL STIMULATION OF GASTRIC SECRETION.  
Miller, Bergeim, Rehfuß, and Hawk: *Am. J. Physiol.*, 52, 1 (1920).

bouillon prepared by dissolving one bouillon cube in hot water. Collect samples of gastric contents at intervals until the stomach is empty as described under Section 5 on p. 386. The samples thus collected may be examined qualitatively for acid, chlorides, pepsin, and rennin; or they may be submitted to the quantitative procedure given on p. 386. If the examination is made quantitative the data may be recorded in the form of a curve such as shown in Fig. 93.

For the *psychical* stimulation, empty the stomach as above. Then instead of having the subjects drink bouillon, simply permit them to *see* and *smell*

an appetizing beefsteak while it is being cooked. Collect samples of gastric contents as above, plot a curve and compare with Fig. 94.

## Gastric Analysis

The method of gastric analysis which was in vogue clinically for years entailed the feeding of a standard test meal, the removal of the complete stomach contents at the end of a one-hour period, and the analysis of the material so removed. That this method is inaccurate has been repeatedly demonstrated in the senior author's laboratory and elsewhere. Furthermore, owing to the bulk of the old form of stomach tube and the discomfort occasioned by its use, it is impossible to follow the whole cycle of digestion and estimate, step by step, the exact changes which take place in the stomach after the introduction of definite food mixtures into that organ.

Realizing the inadequacy of the procedure entailed in the old method of gastric analysis, an improved procedure was developed by Dr. Martin E. Rehfuss in the senior author's laboratory. This so-called Fractional Method entails the analysis of samples of material withdrawn from the stomach (by syringe) at short intervals for a period of two hours or more (until the stomach is empty) after the ingestion of the test meal. By this means the observer is able to follow the entire cycle of gastric digestion and is not limited, as in the old method, to information derived from the analysis of a single sample of stomach contents withdrawn at the end of one hour. That the acid values obtained by the old method may be grossly misinterpreted and lead to an incorrect diagnosis is indicated by the diagram shown in Fig. 95.

It is set forth in Fig. 95 that various types of abnormal gastric secretion would be considered normal on the basis of a single examination at the end of one hour, whereas the application of the fractional method reveals an abnormality of the secretion. The removal of samples of gastric contents at short intervals, for a period of two hours or more after a test meal, is made possible by the use of a modified stomach tube<sup>1</sup> of small diameter (No. 12 French tubing) and fitted with a metal tip. The tip is slotted with large perforations, the diameter of each being equivalent to the maximum bore of the tubing. Such a tube can be left in the stomach through the entire cycle of gastric digestion without inconvenience to the patient. The Rehfuss stomach tube is shown in Fig. 96.<sup>2</sup> Lyon suggested a modified tip.

A tube much favored in England is that devised by Ryle.<sup>3</sup> This consists

of a small-bore rubber tube with a blind end, into which is inserted an oval weight of lead. Holes are punched in the rubber tube just above the weight.

Other tubes or plastic catheters have been employed in gastric analysis.<sup>4</sup> Certain of these (Levin) may be passed through the nose. Such tubes are

useful in rapidly demonstrating the absence or presence of free hydrochloric acid in the stomach contents.

A method of determining gastric acidity *without intubation* has also been suggested by Segal and his associates.<sup>5</sup> An editorial in the Journal of the American Medical Association<sup>6</sup> discusses the method as follows:

<sup>4</sup> One of these, the *Sawyer tube*, was developed at the Mayo Clinic by Miss Catherine Sawyer.

<sup>5</sup> Segal, Miller, and Morton: *Proc. Soc. Exptl. Biol. Med.*, **74**, 218 (1950); Segal, Miller, Morton, and Young: *Gastroenterology*, **16**, 380 (1950); Segal: *Med. Clin. N. Amer.*, **35**, 593 (1951).

<sup>6</sup> *J. Am. Med. Assoc.*, **146**, 260 (1951).

“Segal and his associates recently described a test for determining the presence or absence of free hydrochloric acid in the stomach without subjecting the patient to intubation. The principle of the test lies in the use of a cation exchange resin to which is attached a special indicator cation that can be readily identified when it is released from the compound by an ion exchange reaction. Clinical trials have been based on administration of a quininium exchange indicator compound<sup>7</sup> prepared by subjecting an acid-conditioned cation exchange resin to a solution of quinine hydrochloride. By this treatment, quinine replaces the hydrogen cations of the carboxylic acid groups present in the resin. If free hydrochloric acid is present in the stomach, the quinine will be replaced by hydrogen ions and the liberated quinine will be absorbed into the body and can later be detected in the urine. Smaller amounts of quininium cations may be displaced by the cations present in the secretions of the small intestine. However, these quininium cations can be differentiated from those displaced by the hydrogen ions in gastric juice by the time of appearance and the amount of quininium cations in the urine.

This procedure is more pleasant for the patient than the conventional intubation method. Its simplicity suggests its usefulness as a screening test to select achlorhydric subjects in the gastric cancer age group for further investigative studies.”

PROPERTIES AND COMPOSITION OF HUMAN GASTRIC JUICE

|                                       | <i>Appetite Juice</i> | <i>Residuum</i> |

An apparatus has also been devised<sup>8</sup> for the determination of intra-gastric conductance and temperature. The apparatus is also provided with an aspiration tube similar to that of the Rehfuß tube which makes possible the removal of samples of gastric contents for chemical analysis.

For a long time the consensus, based principally upon the work of the Pavlov school, was to the effect that the gastric juice of normal man had an average acid concentration of 0.2 per cent hydrochloric acid, whereas the gastric juice of the dog and cat had an average acid concentration of 0.4 to 0.5 per cent hydrochloric acid. These experiments were based principally upon the examination of the pure gastric juice of the lower animals as compared with the stomach contents of man. Later experiments, however, demonstrated that the acid concentration of the *freshly*

<sup>7</sup> Diagnex (Squibb) is useful in this connection. The appearance of quinine in the urine within two hours after the administration of Diagnex shows the presence of HCl. The absence of quinine within this period indicates achlorhydria.  
<sup>8</sup> Bergeim: *Am. J. Physiol.*, 45, 1 (1917).

*secreted* gastric juice of man is similar to that of the dog; i.e., 0.4 to 0.5 per cent hydrochloric acid. Boldyreff claimed that this initial high acidity of the human gastric juice is normally lowered to the "optimum acidity" of 0.15 to 0.2 per cent by regurgitation of alkaline fluids (bile, pancreatic, and intestinal juices) from the intestine. This constitutes what Boldyreff termed "the automatic regulation of gastric acidity." This claim has been amply substantiated. Both bile and trypsin are easily identified in the stomach contents of man after the introduction of 0.5 per cent hydrochloric acid into the empty organ.

The composition of human gastric juice and of the residuum (see p. 384) is given in the table on p. 377.

## THE USE OF INDICATORS IN GASTRIC ANALYSIS

Indicators are used in gastric analysis for two main purposes: (1) For the colorimetric determination of the pH of gastric contents, and (2) as an aid in the measurement of gastric acidity by titration. The use of indicators for the first purpose is identical in principle with their use in this connection with other fluids, and is described in detail on p. 37. The practical details in connection with gastric analysis are presented on p. 379.

The primary objective in the titration of gastric acidity is to determine the amount of unneutralized hydrochloric acid present ("free hydrochloric acid"), in the possible presence of other acids which while titratable are nevertheless so much less highly ionized than hydrochloric acid that they contribute little or nothing to the hydrogen-ion concentration of the solution. It is the hydrogen-ion concentration (i.e., the pH) of the gastric contents which to a large extent determines whether or not the physiological functions of the gastric secretion will be served, and hydrogen ions in concentration sufficient to maintain a normal pH can come only from a highly ionized acid such as hydrochloric acid. Thus gastric function can be evaluated in terms of the presence and amount of free hydrochloric acid. Since the concentration of free hydrochloric acid determines the pH, it is clear that a pH measurement will frequently give as much information as a titration, and increasing use of pH determination in this connection is being made clinically, particularly in view of the ease with which precise pH determinations may be made with the modern electronic pH meters (see Chapter 1).

The establishment by titration of the presence and amount of free hydrochloric acid in the presence of other titratable acids is based on the fact that hydrochloric acid is completely dissociated in solution, the hydrogen ions from this dissociation reacting with the added OH ions before any undissociated acid present can ionize and so react. Thus the amount of alkali added up to the point of practically complete neutralization of the hydrochloric acid present should be distinguishable from that necessary for the remaining acid or acids. That this is so is evident from an inspection of the titration curve for hydrochloric acid as compared with that for a typical weak acid such as acetic acid; such curves are shown in Fig. 11 of Chapter 1. From an inspection of these curves it can be seen that as standard alkali is added to a solution containing hydrochloric

acid, the pH of the solution changes relatively little until most of the acid is neutralized, increasing from pH 1 to about pH 2, when about three-fourths of the acid has been neutralized. As the titration continues, at about pH 3.5 or so it is clear that practically all of the acid has been titrated; stopping the titration at this point gives a value for the acid present which is almost indistinguishable from the value obtained if the titration were carried to the end point with such indicators as methyl orange, litmus, or phenolphthalein.

The situation is quite different if a weak acid, such as acetic acid for example, is being titrated. In the case of acetic acid, the solution has a pH of about 3 before any alkali has been added, this pH corresponding to the relatively small (about 1 per cent) ionization of the acetic acid molecules. As the pH is increased by the addition of alkali, more of the acetic acid dissociates to give hydrogen ions which are capable of reacting with the added OH ions, until ultimately sufficient alkali has been added to neutralize all of the acid initially present. But it will be noted that the end point of this titration (i.e., the pH at which equivalent amounts of alkali and acid are present) is not pH 7 but rather nearer pH 8.5. Thus, in order to titrate such an acid as this, it is necessary to use an indicator which changes color at about pH 8.5; phenolphthalein is such an indicator.

From what has just been said, it follows that if a mixture of hydrochloric acid and some weak acid or acids is being titrated with standard alkali, the buret reading at pH 3.5 or thereabouts will be a measure of the hydrochloric acid present, while the reading at pH 8.5 will be a measure of the total acidity of the solution. It is thus possible to distinguish quantitatively between these two types of acidity provided that means of indicating the pH of the solution are available. This may be done using a pH meter; it is much more common to select an indicator whose color change lies at the pH range desired. Of the various indicators which have been proposed for this purpose in gastric analysis, *Töpfer's reagent* (dimethylaminoazobenzene) and phenolphthalein are almost universally used. Töpfer's reagent has a color change from red to yellow over the pH range 2.9 to 4.0 (see Table), the intermediate color of salmon pink being noticeable at approximately pH 3.3. Thus if gastric contents are titrated with alkali to the color change with Töpfer's reagent, a measure of the free hydrochloric acid present will be obtained, the value being uninfluenced by any weak acids which may be present. If the titration is then continued to the color change with phenolphthalein (pH 8.5), the total acidity is determinable.

Töpfer's reagent has a number of disadvantages; the color change is not sharp and requires a certain amount of familiarity before the proper end point is routinely obtainable; furthermore, the color fades rapidly at the end point and thus precludes the setting up of pH controls for the more precise establishment of the end point. Other indicators have been proposed, such as thymol blue (red, becoming yellow at pH 2.8), and bromophenol blue (yellow, beginning to turn blue at pH 3.4 or so), but in the authors' experience of teaching medical students and technicians the routine of gastric titrations, neither of these has proved so satisfactory as Töpfer's reagent.

In the above discussion acetic acid was used as an example of a typical weak acid, to illustrate the principles involved in a gastric titration. In actual practice the weak acids which may be found in gastric contents include *protein hydrochloride* (so-called "combined hydrochloric acid"), *acid phosphates*, and various organic acids such as *lactic*, *citric*, etc., after fermentation or the ingestion of certain foods. At one time the mistaken notion prevailed that by the suitable use of various indicators it was possible to differentiate between these components of the weak-acid fraction of gastric contents. This is not true, since the titration curves of these various components overlap to such an extent that it is impossible to differentiate between the contribution of each to the total acidity, and the concept should be abandoned. Even the distinction between free mineral acid and weak organic acids becomes less sharp if the organic acids have an appreciable ionization at pH 3 or so, as is the case for example with lactic acid. The presence of significant amounts of such organic acid in gastric contents is quite unusual; should it occur, the determination of volatile chloride is of value in establishing the extent of acidity due to hydrochloric acid.

It is occasional practice in the titration of relatively pure gastric contents to subtract the value for the free acidity from that of the total acidity and call the difference the "combined acid." The validity of this is questionable; even assuming that the difference between free and total acid is partly due to acid which has reacted with protein to form protein hydrochloride, it is clear that the amount of acid which has so reacted is measurable only by titrating the solution to the isoelectric point of the protein; further titration beyond this pH represents the formation of alkali salt of protein and will depend on the amount and nature of protein present, without reference to how much hydrochloric acid has been "combined" with the protein. Actually, the difference between free and total acid is more a measure of the buffer power of the gastric juice than anything else. From a practical point of view, therefore, it would appear that the requirements of gastric analysis, at least in so far as gastric acid is concerned, are largely met by measurement of either the free acid or the pH.

The table on p. 381 lists the characteristics of those indicators which have found application in gastric analysis and for other purposes. Experiments which follow illustrate the application of the principles just presented.

**Tests with Indicators.** Prepare a series of solutions of varying acidities as outlined in the following table, p. 382. Introduce 5- or 10-ml. portions of each of these into a series of test tubes and to each add a few drops of a solution of thymol blue. Make a note of the colors produced, in the spaces left for this purpose. In the same way test the other indicators mentioned, in order, in each case using a few drops of the indicator solution.

Are the following assumptions, on which the use of certain of these indicators in gastric analysis is based, borne out by your findings?

1. That Töpfer's reagent (dimethylaminoazobenzene) gives its characteristic pinkish-red color only in the presence of free HCl.

- 2. That Congo red can be used to distinguish between strong acids, moderately weak acids, and very weak acids.
- 3. That thymol blue may be used as an indicator in the titration of both free and total acid.
- 4. That alizarin may be used in titrations where the end point is at a pH just acid to pH 7 rather than just beyond pH 7.
- 5. That phenolphthalein can be used in titrating total acidity, that is, acidity due to mineral and organic acids, acid salts, and combined acid.
- 6. That Günzberg's test is in certain respects the most satisfactory one for free HCl.
- 7. That "combined acid" (protein hydrochloride) is an acid of approximately the strength of acetic acid.

| Indicator                         | pH Range  | Color Change      |
|-----------------------------------|-----------|-------------------|
| Thymol blue (acid range).....     | 1.2- 2.8  | Red-yellow        |
| Töpfer's reagent.....             | 2.9- 4.0  | Red-yellow        |
| Bromophenol blue.....             | 3.0- 4.6  | Yellow-blue       |
| Congo red.....                    | 3.0- 5.0  | Blue-red          |
| Methyl orange.....                | 3.1- 4.4  | Orange red-yellow |
| Bromocresol green.....            | 4.0- 5.6  | Yellow-blue       |
| Methyl red.....                   | 4.2- 6.3  | Red-yellow        |
| Litmus.....                       | 4.5- 8.3  | Red-blue          |
| Chlorophenol red.....             | 5.0- 6.6  | Yellow-red        |
| Alizarin red.....                 | 5.0- 6.8  | Yellow-red        |
| p-Nitrophenol.....                | 5.0- 7.0  | Colorless-yellow  |
| Bromocresol purple.....           | 5.4- 7.0  | Yellow-purple     |
| Bromothymol blue .....            | 6.0- 7.6  | Yellow-blue       |
| Phenol red.....                   | 6.6- 8.2  | Yellow-red        |
| Neutral red.....                  | 6.8- 8.0  | Red-yellow        |
| Cresol red.....                   | 7.2- 8.8  | Yellow-red        |
| Meta cresol purple.....           | 7.6- 9.2  | Yellow-purple     |
| Thymol blue (alkaline range)..... | 8.2- 9.8  | Yellow-blue       |
| Phenolphthalein.....              | 8.3-10.0  | Colorless-red     |
| Alizarin yellow.....              | 10.0-12.0 | Colorless-yellow  |
| Tropaeolin O.....                 | 11.1-12.7 | Yellow-orange     |

**Special Test for Free HCl (Günzberg's Test).** Perform the following test on Solutions 1 to 4 of the table and tabulate the results. Place 1 to 2 drops of Günzberg's reagent<sup>9</sup> in a small porcelain evaporating dish and carefully evaporate to dryness over a low flame. Insert a glass stirring rod into the mixture to be tested and draw the moist end of the rod through the dried reagent. Warm again gently and note the production of a purplish-red color in the presence of free hydrochloric acid. This test differs markedly from the use of indicators in that the reaction is not determined by the pH of the solution, but is based on the fact that hydrochloric acid of any strength whatever reaches a "constant boiling" concentration of about 20 per cent on evaporation. At this strength of acid the ingredients of the reagent condense to form a purplish-red compound. The reaction is thus highly specific for hydrochloric acid in gastric juice.

<sup>9</sup> See Appendix.

TABULATION OF RESULTS OF TESTS ON INDICATORS\*

\* Indicator solutions. *Thymol blue*, *Cresol red*, *Bromophenol blue*, *Bromocresol green*, *Chlorophenol red*, and *Bromothymol blue*, 0.04 g. in 100 ml. of alcohol. *Methyl orange*, 0.1 g. in 100 ml. of water. *Töpfer's reagent*, 0.5 g. of dimethylaminoazobenzene in 100 ml. of 95 per cent alcohol. *Congo red*, 0.5 g. in 90 ml. of water and add 10 ml. of 95 per cent alcohol. *Alizarin*, 1 g. of sodium alizarin sulfonate in 100 ml. of water. *Phenolphthalein*, 1 g. in 100 ml. of 95 per cent alcohol.

† Combined HCl. Treat 0.4 per cent HCl with a small amount of Witte's peptone and boil until the solution no longer gives a blue but only a brown color with Congo-red paper.

‡ Make up solutions of potassium dihydrogen phosphate and of disodium hydrogen phosphate of M/15 strength. See p. 35. To prepare the acid phosphate solution used in the test, mix 1 part of the solution of the disodium salt with 9 parts of the solution of the dihydrogen phosphate. For the basic phosphate solution the proportions are 20:1; for the solution of pH 7, the proportions are 6:4. Do not attempt to use distilled H<sub>2</sub>O alone as a pH 7 solution. (Why not?)

§ Borate-NaOH solution. Prepare a borate solution by dissolving 12.404 g. of pure boric acid (0.2 mol.) in 100 ml. of N NaOH solution and dilute with water to a liter. Prepare the borate-NaOH solution by mixing 6 parts of the borate solution with 4 parts of 0.1 N NaOH.

**Differential Titration of a Mixture of Strong and Weak Acids.** (a) Titrate a 5-ml. portion of 0.1 N acetic acid with 0.1 N sodium hydroxide, using phenolphthalein as indicator. (b) Titrate a 5-ml. portion of 0.1 N hydrochloric acid, using phenolphthalein. (c) Titrate a 5-ml. portion of 0.1 N hydrochloric acid, using Töpfer's reagent (one drop) as indicator. The end point is a salmon-pink shade, intermediate between red and yellow. Is there any significant difference in the titer of the hydrochloric acid as compared with the value obtained in (b)? (d) Now mix 5-ml. portions of 0.1 N acetic acid and 0.1 N hydrochloric acid in a flask, add Töpfer's reagent, and titrate with alkali to the salmon-pink end point. Read the buret, add a drop of phenolphthalein to the contents of the flask, and continue the titration with alkali until the pink color of the phenolphthalein end point can be seen to be superimposed on the clear yellow color of the Töpfer's reagent. Read the buret again. This reading represents the "total acidity." The first reading is a measure of the HCl present, and the difference between the first and final readings represents the acidity due to the weak acid (acetic, in this case). Compare the values you obtain in this differential titration with those obtained by separate analysis in parts (a) and (c) above.

## THE FRACTIONAL METHOD OF GASTRIC ANALYSIS

Since 1914, when the first experiments entailing the use of the fractional method were reported from the senior author's laboratory, the method has been widely adopted both in this country and abroad. This widespread use by a large number of workers has resulted in much discussion of the method. On the basis of this large experience certain modifications in the original technique are here presented. In its major details, however, the method remains as originally carried out, and in the opinion of the authors constitutes the best available method for the clinical examination of the stomach.

When an Ewald test meal is given to normal individuals a curve such as Curve (1) in Fig. 95 is usually obtained. The curve may vary within certain limits depending on individual idiosyncrasies, but it is usually found to follow the curve depicted, and the meal normally leaves the stomach in two and one-half hours. Pathologically every variation occurs, in time of evacuation as well as in the character of the curve and the quantity of the secretion elaborated. Fig. 95 represents some of the possibilities of pathological cases, but a consideration of their interpretation is outside the purpose of the present volume. It is evident, however, that the cycle of gastric digestion is a constantly changing one, and no information concerning the trend of digestion can be obtained by an examination at only a single stage of digestion. Marked changes may precede or follow that stage.

Low acidities may be found in carcinoma, in atonic dyspepsia and in pernicious anemia. However, anacidity of itself is not necessarily of pathological significance. A tendency toward high acidities may be found, though not constantly, in cases of gastric and duodenal ulcers, especially those occurring in the neighborhood of the pylorus and inducing some degree of obstruction. High acidities may be induced reflexly in gallbladder disease and appendicitis.

As this is written, one of the favorite means used to combat the high acid tendency of ulcer is the chemical substance called *Banthine* ( $\beta$ -diethylaminoethylxanthene-9-carboxylate methobromide).<sup>10</sup> However, there are those who do not believe that Banthine is the final answer to the ulcer problem.<sup>11</sup> It is suggested that the drug

<sup>11</sup> Ruffin: *Gastroenterology*, 17, 589 (1951); Levin, Kirsner, and Palmer, *Gastroenterology*, 21, 339 (1951).

should be used to supplement conventional methods of treatment rather than to replace them. Pro-banthine and Prantal have also been recommended for use in ulcer therapy. In the past, roentgen therapy as well as the use of radioactive phosphorus ( $P^{32}$ ) and radioactive iodine ( $I^{131}$ ) have been used with indifferent success to suppress gastric acidity clinically. *Radioactive krypton* may possibly prove more effective for this purpose.<sup>12</sup> However this has not been definitely proved.

Some gastroenterologists have found the *gastrophotor* useful in the study of ulcer. This is a tiny camera which may be swallowed by the patient. By its use 16 pictures of various sections of the stomach walls may be taken at the same time.

## OBTAINING THE SAMPLES

**1. Introduction of the Stomach Tube.** Whereas the large tube is directly inserted by propulsion, the Rehfuß tube is swallowed in the natural manner with the aid of gravity. The tube may be passed in one of three ways, viz., (1) lubricated; (2) with the aid of fluid; (3) after the throat is cocainized. When passed by the first method the tip of the tube, after thorough lubrication with glycerol or liquid petrolatum is held between the thumb and forefinger and placed on the tongue. Then with the aid of the forefinger the tip is pushed backward until it reaches the root of the tongue and is engaged in the oropharynx. Then the patient is encouraged to breathe deeply through the nose and to swallow persistently while the tube is slowly fed into the mouth. After slight discomfort in the pharynx and its passage past the level of the cricoid cartilage, practically no discomfort is felt. This method is used when it is essential that the pure gastric secretion or residuum be obtained. Ordinarily, however, it is much easier to swallow the tube by the second method. This method consists in placing the tip in the oropharynx and then giving the patient a measured quantity of water or tea to swallow. The movements induced by the swallowing carry the tube rapidly to the stomach with a minimum of discomfort. When an Ewald meal (see p. 385) is given, part of the tea may be reserved for swallowing the tube. This procedure makes it scarcely more arduous than the swallowing of food. Should the patient, however, be extremely neurotic or the unfortunate possessor of marked pharyngeal hyperesthesia, cocaine hydrochloride in 2 per cent aqueous solution may be applied to the throat, rendering the passage of the tube practically insensible. When the tube has entered the stomach, aspiration of the material shows the characteristic gastric contents. Should the tip remain in the esophagus through transient cardiospasm or other cause, aspiration results in the removal of only a very small specimen having all the characteristics of the pharyngeal and esophageal secretions.

The clinician should see to it that the tube is so placed that the tip reaches the lower pole of the stomach. Furthermore, *the tip should remain in this position throughout the duration of the test*. By placing the tube in this manner, representative specimens and accurate data may be obtained.

It has been shown that the gastric response to the fractional method when properly performed is similar for the same individual on different days<sup>13</sup>

Bloomfield and Keefer have suggested a method for the "continuous quantitative estimation of gastric secretion and discharge in man."

**2. Removal and Analysis of Residuum.** If the so-called empty stomach is examined in the morning before any food or drink has been taken it will be found to contain considerable material, which is termed *residuum*. Before a

<sup>12</sup> Steinfield: *Proc. Soc. Exptl. Biol. Med.*, 81, 636 (1952).

<sup>13</sup> Ryle: *Gastric Function in Health and Disease*, London, Oxford University Press, 1926.

test meal is introduced into the stomach, this organ should be emptied. If this is not done we cannot consider the samples withdrawn after the test meal is eaten as representing the secretory activity of the gastric cells under the influence of the stimulation of the test meal. It has been generally recognized, clinically, that a residuum greater than 20 ml. is pathological. Such a volume has been considered as indicative of hypersecretion, and this in turn in many cases indicates an organic lesion. The observations indicating that a residuum of over 20 ml. was pathological were made upon residuums removed by means of the old type of stomach tube which does not completely empty the stomach. When the residuum is completely removed by means of the Rehfuß tube it has been demonstrated that the *normal* residuum is practically always over 20 ml., the average for both men and women being about 50 ml. The normal residuum has been found to possess all the qualities of a physiologically active gastric juice with an average total acidity of 30 and an average free acidity of 18.5. The residuum is often colored by bile. This is particularly true if the fluid has a relatively high acidity. Trypsin is also generally present. These findings indicate regurgitation (see p. 390). Pathological residuums may contain blood, pus, and mucus and may also show food retention, indicative of delayed evacuation. In carcinoma the residuum frequently has a foul odor. The quantity may also be much increased owing to hypersecretion. A residuum of large volume possessing a total acidity value of 70 or over may indicate ulcer.

Remove the residuum as directed under (5) on p. 386, and analyze the fluid according to methods outlined on p. 386.

**3. Feeding the Test Meal.** Before making an analysis of the stomach contents it is customary to introduce something into the stomach which will stimulate the gastric cells. The response to this stimulation is then measured clinically by the determination of total acidity, free acidity, and pepsin in the stomach contents. Many forms of test meal have been used.

The test meal most widely employed is the Ewald test meal. This consists of 2 pieces (35 g.) of toast and 8 ounces (250 ml.) of tea.

Inasmuch as it was demonstrated in the senior author's laboratory that water gave a similar gastric stimulation to that produced by the Ewald meal, it was suggested that a simple water meal might be substituted for the Ewald meal. This water meal also has the added advantage of enabling one to determine the presence of food rests and to test more accurately for lactic acid, blood, and bile. Ryle<sup>14</sup> prefers to use oatmeal gruel (1 pint). Another test meal favored in certain English hospitals consists of 20 g. citrus pectin, 35 g. sucrose, 60–70 mg. phenol red and sufficient caustic soda to raise the pH to 6.5 in one liter of distilled water.<sup>15</sup> The alcohol test meal has also been suggested.<sup>16</sup> This consists of 200 ml. of 5 per cent ethyl alcohol. Doses of 0.5 to 1 mg. of histamine hydrochloride injected subcutaneously are effective in stimulating gastric secretion and may help to differentiate between true and "apparent" achylia gastrica.

**4. Feeding the Retention Meal.** In order to obtain more information regarding gastric motility than is furnished by the ordinary test meal described above, the patient may be fed a so-called retention meal. This meal is fed in place of the regular evening meal and contains substances readily detected.

<sup>14</sup> Boil 2 tbsp. of oatmeal in a quart of water until the total bulk is reduced to 1 pint. Strain through coarse muslin. Season with salt as desired.

<sup>15</sup> Hunt: *Lancet*, 257, 794 (1949), and *J. Physiol. (London)*, 113, 169 (1951).

<sup>16</sup> Ehrmann: *Am. J. Digestive Diseases*, 13, 23 (1946).

In the morning before breakfast (7 to 8 A.M.), remove the stomach contents (residuum, see p. 384) by aspiration and examine for food rests. The normal stomach should give no evidences of food retention. A satisfactory retention meal consists of 4 ounces each of boiled string beans and rice. Diets containing prunes, raspberry marmalade, lycopodium powder, etc., have also been employed. In many instances an ordinary mixed diet will serve the purpose.

**5. Removal of Samples of Stomach Contents.** At intervals of exactly 15 minutes from the time the test meal is eaten until the stomach is empty, 5- to 6-ml. samples of gastric contents are withdrawn from the stomach by means of aspiration. (A few milliliters of air is blown down the tube in order that the tube shall be empty when the next sample is drawn.) If the stomach is not empty at the end of three hours, the remaining stomach contents may be withdrawn and measured.

In order to facilitate the mixing of the stomach contents and the withdrawal of a more representative sample, the stomach contents should be aspirated back and forth four times before taking the sample for analysis. Some clinicians advise that the stomach contents be mixed by physical manipulation just prior to aspiration.

In the removal of samples from the stomach, it is essential that very little traction be employed. To completely empty the stomach, aspiration is practised in four positions: (*a*) on the back, (*b*) on the stomach, (*c*) on the right side, and (*d*) on the left side. This results in complete evacuation of the stomach. Three tests may be employed to determine whether the stomach is empty: (1) No more material can be aspirated in any position. (2) Injection of air and auscultation over the stomach with a stethoscope reveals a sticky rale and not a series of gurgling rales such as is heard when there is material in the stomach. (3) Lavage or irrigation through the tube shows the absence of all food in the stomach.

## EXAMINATION OF THE SAMPLES

The old methods of gastric analysis involved the collection (by analysis and calculation) of data regarding several types of acidity. It has already been pointed out (p. 380) that the validity of such data is questionable. The modern tendency among clinicians is to lay particular emphasis upon the values for total acidity, free acidity, and pH. Chloride partition may also give some information. The determination of the peptic activity is also of occasional value as well as the demonstration of the presence or absence of occult blood, lactic acid, mucus, food rests, etc.

Strain each sample through fine-mesh cheesecloth.<sup>17</sup> Examine the residue for mucus, blood,<sup>18</sup> and food rests. Use the strained stomach contents for the determination of total acidity, free acidity, and peptic activity by methods which follow.

**1. Determination of Total Acidity. Principle.** The indicator used is phenolphthalein. Since the indicator reacts with mineral acid, organic acid, combined acid, and acid salts, the values obtained represent the *total acidity* of the solution.

**Procedure.** Measure 1 ml. of the strained stomach contents by means of an Ostwald pipet and introduce it into a low-form 60-ml. porcelain evaporating

<sup>17</sup> Any examination required for microscopic constituents should be made on the original (unstrained) gastric contents. Tests for occult blood may be made on the *sediment* if desired.

<sup>18</sup> The detection of blood is rather more satisfactory in the residue than in the strained fluid.

dish. Dilute with 15 ml. of distilled water. Add 2 drops of a 1 per cent alcoholic solution of phenolphthalein and titrate with 0.01 N sodium hydroxide until a faint pink color is obtained which persists for about 2 minutes. Take the buret reading and calculate the total acidity.

**CALCULATION.** Note the number of milliliters of 0.01 N NaOH required to neutralize 1 ml. of stomach contents, and multiply it by 10 to obtain the number of milliliters of 0.1 N NaOH necessary to neutralize 100 ml. of stomach contents. This is the method of calculation most widely used.

**2. Determination of Free Acidity: Principle.** An indicator is selected which changes color at sufficiently low pH values so that the end-point corresponds to the neutralization of all highly ionized acid only, as discussed on p. 378. The indicator most widely used is Töpfer's reagent; its advantages and disadvantages have been presented on p. 379. The use of Sahli's reagent, a mixture of potassium iodide and iodate which liberates free iodine in the presence of a sufficiently high concentration of hydrogen ions, has been suggested in place of Töpfer's reagent. The liberated iodine is titrated with thiosulfate solution and the end point is very sharp. Unfortunately, Sahli's reagent reacts to a certain extent with weak organic acids so that high values are obtained for example after the ingestion of acid fruits. A procedure using Sahli's reagent is given in the eleventh edition of this book.

**Procedure.** By means of an Ostwald pipet measure 1 ml. of the strained stomach contents and introduce it into a low-form 60-ml. porcelain evaporating dish. Dilute with 10 ml. of distilled water. Add 2 drops of Töpfer's reagent (0.5 per cent alcoholic solution of dimethylaminoazobenzene) and titrate with 0.01 N sodium hydroxide to a salmon-pink color. If the sample gives a yellow color on the addition of Töpfer's reagent, it has no free acid present. The end point may require practice in identification. The use of comparative buffered colorimetric standards to control the end point has been suggested.<sup>19</sup> Care should be taken against the possibility of color fading. The reading of the buret at the end point is a measure of the free acidity.

It is common clinical practice to use this same sample for the determination of total acidity. To do this, add 2 drops of a 1 per cent alcoholic solution of phenolphthalein, and continue the titration until the pink color change of the phenolphthalein is superimposed on the yellow color of the Töpfer's reagent. The buret reading at this point is a measure of the total acidity.

**CALCULATION.** Note the number of milliliters of 0.01 N sodium hydroxide required to reach the end-point color with Töpfer's reagent. Multiply this by 10 to obtain the number of milliliters of 0.1 N sodium hydroxide necessary to neutralize the free acid in 100 ml. of gastric contents. This value also corresponds to the free acidity expressed in degrees or in milliequivalents of acid per liter. In a similar way, the buret reading at the phenolphthalein end point can be used to calculate the total acidity.

**3. Determination of Hydrogen-ion Concentration of Gastric Contents. Principle.** Inasmuch as the hydrogen-ion concentration of the gastric contents is a determining factor in peptic digestion the estimation of pH is coming into wider use in gastric analysis. Simple colorimetric methods are available for this purpose, as is the convenient electrometric pH meter. The measurement of pH gives information of real value and the test-paper method especially is so convenient that it may often be the method of choice.<sup>20</sup> Determinations of pH do not, however, displace titration methods, since the latter give additional information.

<sup>19</sup> Berk, Thomas, and Rehfuss: *Am. J. Digestive Diseases*, **9**, 106 (1942).

<sup>20</sup> Prepared outfits for both the indicator solution and test paper methods may be obtained from most larger laboratory supply houses.

## (a) COLORIMETRIC METHOD OF SHOHL AND KING.

**Procedure.** Prepare Clark and Lubs standard solutions for pH 1.4, 1.6, 1.8, 2.0, 2.4, 3.0 (see Chapter 1). Transfer 2 ml. of filtered or centrifuged gastric contents to a test tube 11 mm. in diameter. Add 2 drops or 0.04 ml. of 0.2 per cent thymolsulfonephthalein in 95 per cent alcohol. Compare with equal amounts of standard solutions treated in the same way in similar test tubes. If the sample is more acid than pH 1.4, lower standards may be prepared. Using the Ewald test meal it may be said in a general way that pH 1.4 represents a high acidity; from 1.6 to 1.8, moderate normal acidity; from 2.0 to 2.4, low acidity; and 3.0 or higher, anacidity.

## (b) METHOD OF DENIS AND SILVERMAN USING TEST PAPERS.

**Procedure.** Prepare test papers as follows. A solution of dye (dimethylaminoazobenzene 0.5 per cent or 0.1 per cent thymol blue) is poured over a sheet of filter paper six inches in diameter, the excess dye allowed to drain off, and the paper dried quickly by holding it in front of a rapidly revolving electric fan. Prepare the two kinds of paper, cut in strips approximately 1 by  $\frac{1}{4}$  inch, and place in a stoppered bottle. Keep away from light and laboratory fumes. Smooth, ashless quantitative paper of the highest grade should be used.

Pour some of the material to be tested over the end of a test paper. The colors may be compared with those obtained from similar papers dipped in the standard solutions mentioned in the method of Shohl and King above. However, with some practice this will be unnecessary. All readings should be made at once. The table given below will serve as a guide in the interpretation of results. It gives test-paper results as compared with number of ml. of 0.1 N NaOH that would be required to neutralize 100 ml. of a solution of the H-ion concentration found, if all the acid were free HCl.

| <i>Indicator</i>      | <i>pH</i> | <i>Color</i>     | <i>Ml. 0.1 N<br/>NaOH<br/>Required</i> | <i>Remarks</i> |
|-----------------------|-----------|------------------|----------------------------------------|----------------|

**4. Determination of Peptic Activity.**

(a) PHOTOMETRIC METHOD OF RIGGS AND STADIE. In this method the enzyme activity is measured photometrically as the decrease in turbidity of a standardized, homogenized suspension of coagulated egg white under specified conditions. Accurate measurement is possible down to a level equivalent to 1  $\mu$ g. of crystalline pepsin. Protein hydrolysis so measured follows a monomolecular course and hence the enzyme activity is expressed as a velocity constant. This method is particularly adapted to clinical studies. For details of procedure see the original article.<sup>21</sup>

<sup>21</sup> Riggs and Stadie: *J. Biol. Chem.*, 150, 463 (1943).

(b) **HEMOGLOBIN METHOD OF ANSON AND MIRSKY. PRINCIPLE.** The pepsin is added to a hemoglobin solution. Unaltered protein is removed with trichloroacetic acid. The amount of digestion products is determined colorimetrically, using phenol reagent, which reacts with tyrosine, tryptophan, and cysteine groups, tyrosine being used as a standard.

For a discussion of the determination of pepsin by viscosimetric and other methods and of pepsin units see Northrop.<sup>22</sup>

**Procedure.** Pipet 5 ml. of a 2 per cent solution of dialyzed ox carbon monoxide hemoglobin<sup>23</sup> in 0.06 N HCl into a 175 by 20 mm. test tube and bring to 35.5° or 25° C. Add 1 ml. of enzyme solution and mix by whirling tube. After 5 minutes add 10 ml. of 4 per cent trichloroacetic acid from another test tube and pour back and forth to mix. Filter through fine paper. To 3 ml. of filtrate in a 50-ml. Erlenmeyer flask add 20 ml. of water, 1 ml. of 3.85 N NaOH, and 1 ml. of phenol reagent (Folin and Ciocalteu. See Chapter 31). The standard consists of 3 ml. of 0.1 N HCl containing 0.15 mg. of tyrosine. (A copper sulfate standard can be used with a red color filter.) Compare colors after 5 to 10 minutes with the standard at 20.

**CALCULATION.**<sup>24</sup> If  $X$  is the reading of the unknown:

$$\text{Pepsin Units} = (0.0194/X) - 0.000147$$

If carried out at 25° C. multiply by 1.82.

(c) **METHOD OF VOLHARD AND LÖHLEIN. PRINCIPLE.** The pepsin is added to casein solution. The unaltered casein is salted out. The filtrate from this contains the digestion products of casein which can be estimated by titration.

**Procedure.** Into each of three flasks (graduated at 300 and at 400 ml.) introduce 11 ml. of N HCl and add water to make not quite 150 ml. With con-

<sup>22</sup> Northrop: *J. Gen. Physiol.*, 16, 41 (1932).

<sup>23</sup> Bubble CO through whipped ox blood. Centrifuge. Siphon off the serum and cells. Wash the corpuscles four times with cold 0.9 per cent NaCl. Add an equal volume of water and a sixth of the total volume of toluol. Bubble the CO through the solution. Shake vigorously. Let stand in the cold over night. Siphon off the hemoglobin layer. Mix gently with a tenth the volume of centrifuged alumina cream (see Appendix). Filter through coarse paper. Dialyze over night in the cold and keep under CO in the cold with toluol as a preservative. Determine N by the Kjeldahl method. Use 17.7 as per cent of N in the hemoglobin. Use mercury instead of copper in the determination and evaporate before digestion to avoid serious foaming. To 3 volumes of 0.1 N HCl add 2 volumes of 5 per cent hemoglobin. This solution may be kept in the cold for 10 days.

The tyrosine used should have been recrystallized and the concentration also determined by the Kjeldahl method. N = 7.74 per cent.

<sup>24</sup> In addition to the 0.15 mg. of tyrosine the standard contains from the reagents an amount of color-producing material equivalent to 0.015 mg. of tyrosine. The color-producing substance in the 3 ml. of filtrate is, therefore, equivalent to  $(20/X)(0.15 + 0.015)$  mg. of tyrosine. Of this 0.015 mg. are due to the color-producing substance in the reagents and 0.01 mg. to the color-producing substance present in the trichloroacetic acid filtrate even when no enzyme is added. The digested hemoglobin in the 3 ml. of filtrate is, therefore, equivalent to  $(20/X)(0.15 + 0.015) - 0.015 - 0.01$  mg. of tyrosine. This value must be multiplied by  $16/3$  to obtain the digested hemoglobin in the whole 16 ml. of filtrate instead of the 3 ml. taken for analysis: it must be divided by 5 to obtain the amount of nonprecipitable digested hemoglobin produced in one minute instead of in 5 minutes; it must be divided by 181, the molecular weight of tyrosine, to obtain the tyrosine equivalent as milliequivalents instead of as milligrams. The relation between the number of pepsin units in 1 ml. of enzyme solution and the colorimeter reading  $X$  is thus:

$$P. U. = \left[ \frac{20}{X} (0.15 + 0.015) - 0.015 - 0.01 \right] \frac{16}{3} \times \frac{1}{5} \times \frac{1}{181} = \frac{0.0194}{X} - 0.000147$$

stant shaking add 100 ml. of the casein solution.<sup>25</sup> Any turbidity must quickly disappear. Add different known amounts of pepsin-containing solution to the three flasks and make up to 300 ml. Keep at 40° C. for one hour. Add 20 per cent sodium sulfate solution to the 400-ml. mark. Filter and titrate 100 ml. of filtrate with 0.1 N NaOH, using phenolphthalein as an indicator.

CALCULATION. Multiply the titration by 4. Correct for blank run without pepsin and for any acidity of the pepsin solution. The square of the result gives units of pepsin. In any pepsin method it is best to determine the amount of unknown required to bring about, in a definite time, the same amount of digestion as a definite amount of a standard solution of pepsin.<sup>26</sup>

**5. Determination of Tryptic Activity.** Trypsin is not a gastric enzyme but occurs in the pancreatic juice (see p. 395). In case of regurgitation of intestinal contents through the pylorus, trypsin would be passed into the stomach. The regurgitation is doubtless of frequent occurrence and may even be a normal mechanism by which gastric acidity is regulated (see p. 378). Trypsin is, therefore, generally present in the contents of the normal human stomach. However, inasmuch as trypsin is destroyed by the pepsin-hydrochloric acid of the gastric juice, determinations of this enzyme must be carried out immediately after aspirations of the gastric contents, particularly where the acidity of the latter is high.

SPENCER'S METHOD.<sup>27</sup> (a) Prepare five reagent tubes, Nos. 1, 2, 3, 4, and 5; more if desired.

To Tubes 1 and 2 add 0.5 ml. of gastric contents (filter if cloudy).

(b) To Tubes 2, 3, 4, and 5 add 0.5 ml. of distilled water.

(c) From Tube 2 remove 0.5 ml. of its mixed contents and add to Tube 3.

Mix thoroughly and add 0.5 ml. from Tube 3 to Tube 4. Repeat for Tube 5. We now have dilutions of gastric contents of 1,  $\frac{1}{2}$ ,  $\frac{1}{4}$ ,  $\frac{1}{8}$ , and  $\frac{1}{16}$ .

(d) To each tube add one drop of phenolphthalein solution (phenolphthalein 1 g.; alcohol (95 per cent) 100 ml.); then drop by drop add a 2 per cent sodium bicarbonate solution until a light pink color is produced.

(e) To Tubes 1, 2, 3, and 4 add 0.5 ml. of casein solution. Tube 5 must receive 1 ml. of casein solution, since it contains 1 ml. of the diluted gastric contents. For the casein solution, dissolve 0.4 g. of casein in 40 ml. of 0.1 N NaOH. Add 130 ml. of distilled water, then 30 ml. of 0.1 N HCl. This leaves the solution alkaline to the extent of 10 ml. of 0.1 N NaOH, minus about 3 ml. neutralized by the casein.

(f) Incubate for five hours at 40° C.

(g) Precipitate the undigested casein by the dropwise addition of a solution of the following composition: glacial acetic acid 1 ml., alcohol (95 per cent) 50 ml., distilled water 50 ml. The tubes in which digestion has been complete remain clear; others become turbid.

(h) The tryptic values are expressed in terms of dilution. Thus, complete digestion in Tube 3 (a dilution of  $\frac{1}{4}$ ) shows four times the tryptic power of undiluted gastric juice; taking this dilution as unity, the undiluted juice has a tryptic value of 4.

<sup>25</sup> Introduce 100 g. of pure casein into a 2-liter flask. Add 1000 ml. of water, shake, and let stand some hours. Add 80 ml. of N NaOH, make up to 2000 ml., and warm gradually until clear. Then heat rapidly to 85°–90° C. to destroy any proteinases and preserve in a stoppered bottle with a little toluol. This solution keeps for a long time.

<sup>26</sup> Treat 10 g. of a good pepsin preparation with 100 ml. of 10 per cent NaCl. Let stand one week at room temperature. Filter. Add an equal volume of glycerol and keep in the ice box. The solution keeps indefinitely.

<sup>27</sup> Elaborated by Spencer in the senior author's laboratory for the specific purpose of determining trypsin in gastric juice.

(i) Controls of boiled gastric contents plus casein solution, and of distilled water plus casein solution, treated as above stated, must show no digestion, and become turbid on addition of the precipitating solution.

**6. Detection of Lactic Acid.** When the acidity of the stomach contents is reduced to a low value there may occur considerable fermentation of carbohydrates which have been introduced into the stomach in the ingested food. This fermentation yields various organic acids, among which lactic acid is particularly prominent. It is important, therefore, in case of low gastric acidity that the stomach contents be examined for lactic acid.

**ETHER-FERRIC CHLORIDE TEST (STRAUSS).** A satisfactory deduction regarding the presence of lactic acid can be made only by removing the lactic acid from interfering material (e.g., hydrochloric acid, protein digestion products, etc.) present in the stomach contents. Lactic acid may be extracted from the stomach contents by ether. The following technique not only serves to detect lactic acid but also gives an approximate idea as to the amount of the acid present.

**Procedure.** Introduce 5 ml. of strained stomach contents into a small graduated separatory funnel, add 20 ml. of ether, and shake the mixture thoroughly. Permit the ether to separate, then allow all the fluid to run out of the separatory funnel except the upper 5 ml. of ether. To this ether extract add 20 ml. of distilled water and 2 drops of a 10 per cent solution of ferric chloride and shake the mixture gently. A slight green color is obtained in the presence of 0.05 per cent lactic acid whereas 0.1 per cent lactic acid yields a very intense yellowish-green color.

**7. Detection of Occult Blood.**<sup>28</sup> **BENZIDINE REACTION.** This is one of the most delicate of the reactions for the detection of blood. Different benzidine preparations vary greatly in their sensitiveness, however. Inasmuch as benzidine solutions change readily upon contact with light it is essential that they be kept in a dark place. The test is performed as follows: To 3 ml. of a saturated solution of benzidine in glacial acetic acid<sup>29</sup> add 2 ml. of the solution to be tested and then 1 ml. of 3 per cent hydrogen peroxide. A positive test is indicated by a green or blue color.

**CONFIRMATORY TEST.** If the mixture contains fat, make neutral or slightly alkaline, and extract by shaking with an equal volume of ether. Discard this ether extract. Make the residue acid with acetic acid and again extract with ether. Pour off ether into a small evaporating dish. Put on a hot water bath with flame turned out and evaporate to dryness. Add a few drops of water, a drop of benzidine solution, and a drop of 3 per cent hydrogen peroxide. A green or blue color indicates blood.

Blood is found in gastric contents in conditions associated with erosion of the mucous membrane, ulcer, and carcinoma. In cases of ulcer the blood may be bright red or may be converted to brown "acid hematin" by the excess of acid which is usually present. In carcinoma the blood forms brownish-black lumps, the so-called "coffee-ground" material.

**8. Detection of Bile in Stomach Contents.** If we accept Boldyreff's theory as to the automatic regulation of gastric acidity under normal conditions by the regurgitation of alkaline material from the intestine, then the presence of bile in the gastric juice does not possess the clinical significance it has been accorded. However, if an

<sup>28</sup> These tests may be made upon the strained stomach contents or upon the solid residue.

<sup>29</sup> Glacial acetic acid is preferable, but alcohol acidified with acetic acid may be used.

ordinary Ewald meal be fed, and bile in any considerable quantity be found throughout the entire course of digestion, it may indicate, pathologically, a stenosis below the level of the common bile duct. The presence of bile is indicated by a yellowish or greenish color of the specimen, changing to a bright green on standing.

## Pancreatic Digestion

As soon as the food mixture leaves the stomach it comes into intimate contact with the bile and the pancreatic juice. Since these fluids are alkaline in reaction and have high buffering qualities, there can obviously be little further peptic activity after they have become intimately mixed with the chyme and have neutralized most of the acidity previously imparted to it by the hydrochloric acid of the gastric juice. The pancreatic juice reaches the intestine through the duct of Wirsung which usually joins with the common bile duct before opening into the intestine near the pylorus.

### STIMULATION OF PANCREATIC SECRETION

**Secretin and Pancreozymin.** Prior to the work of Bayliss and Starling in 1902 it was believed that substances in the intestine stimulated pancreatic secretion through local reflexes from the intestine to the pancreas. This view was based on the observation that the introduction of acid into the intestine was followed by secretion. Bayliss and Starling, however, observed that introduction of acid into a jejunal loop which had been denervated as far as possible still induced secretion. This indicated that the exciting agent acted by way of the blood. Injection of acid directly into the blood did not affect secretion, which must therefore be induced by some substance given off from the mucosa. A substance capable of stimulating secretion by intravenous injection could be extracted from the intestinal mucosa by acid but not by water. Apparently the mucosa is stimulated by the acid of the gastric chyme to liberate *secretin* which passes by way of the blood stream to the pancreas causing it to secrete. This view has been confirmed by many observers, and most clearly by Ivy, Farrel, and Lueth, who found acid applied to transplanted intestinal loops to cause secretion in the transplanted pancreas. The fact that secretin is more readily extractable from the intestinal mucosa by acid than by neutral solvents was interpreted by Bayliss and Starling to mean that the hormone exists in the mucosa as prosecretin. It seems more likely, however, that secretin exists preformed and that the acid chyme serves to release it from its adsorbed state on the colloidal components of the mucosa.

Secretin was the first hormone to have its function clearly established. Tests on the purest secretin preparation so far obtained show it to be a polypeptide, with generally basic properties. Edman and Ågren have demonstrated the existence of 15 (or 16) amino acids in secretin, and

quantitative data are available for seven of these. Although earlier ultracentrifugal measurements indicated a molecular weight of 5000, the values for total sulfur and cystine suggest a figure twice this. The activity of secretin is destroyed by pepsin and trypsin; hence it cannot be given effectively by mouth. Secretin is likewise destroyed on incubation with blood serum, presumably because of the presence of the enzyme secretinase.

Harper and Raper<sup>1</sup> first determined that extracts of duodenal mucosa contain *two* hormonal agencies affecting the external secretory activity of the pancreas. These are (1) secretin, which stimulates the production of fluid and bicarbonate by the pancreatic acini, and (2) pancreozymin, which governs the production of the pancreatic enzymes. Pancreozymin stimulates the output of all pancreatic enzymes, and when injected repeatedly, sustains high enzyme concentrations for prolonged periods. Like secretin, pancreozymin is inactivated by blood serum. Using dogs with a part of the pancreas subcutaneously autotransplanted, Wang and Grossman<sup>2</sup> have observed that products of protein digestion (peptone and amino acids) are most effective in stimulating release of pancreozymin; next most effective are soaps (sodium oleate) and, to a lesser extent, HCl. Carbohydrates are ineffective.

It might be supposed that a failure of the pancreatic secretion would be noted in achylia, in which condition no gastric acid is secreted to bring about the liberation of secretin. This is not the case. Fatty acids formed in fat digestion and protein split products may cause the passage of secretin into the blood stream. For the same reason bile also has some stimulating action on pancreatic secretion.

## PANCREATIC JUICE

The juice as obtained from a permanent fistula differs greatly in its properties from the juice obtained from a temporary fistula, and neither form of fluid possesses the properties of the normal fluid. Pancreatic juice collected from a natural fistula has been found to be a colorless, clear, alkaline fluid (pH 8 or thereabouts) which foams readily. The inorganic salts consist largely of sodium chloride and bicarbonate, in approximately equal amounts; the bicarbonate, obtained in part from blood but largely from metabolic processes within the pancreas,<sup>3</sup> is responsible for the alkalinity of the juice. It is further characterized by containing albumin, globulin, proteose, and peptone; nucleoprotein is also present in traces. The average daily secretion of pancreatic juice is 650 ml. and its specific gravity is 1.008. The fluid contains 1.3 per cent of solid matter and the freezing point is  $-0.47^{\circ}\text{C}$ .

The normal pancreatic secretion contains a variety of different enzymes. Among those which have been well characterized are included the following: (1) The peptide-splitting enzymes trypsin, chymotrypsin, and various carboxypolypeptidases; (2) a polynucleotidase (or nuclease) acting to split nucleic acids into their component mononucleotides; (3)

<sup>1</sup> Harper and Raper: *J. Physiol.*, **102**, 115 (1943).

<sup>2</sup> Wang and Grossman: *Am. J. Physiol.*, **164**, 527 (1951).

<sup>3</sup> Hollander and Birnbaum: *Trans. N. Y. Acad. Sci.*, **15**, 56 (1952).

pancreatic amylase (amyllopsin), an amylolytic enzyme; and (4) pancreatic lipase (steapsin), a fat-splitting enzyme. Other enzymes are doubtless present. It will be noted that pancreatic juice contains enzymes capable of acting on all three classes of foodstuffs—proteins, carbohydrates, and fats. Ivy and co-workers have reported, however, that the concentrations of these enzymes in pancreatic juice can be markedly influenced by diet. Thus, animals receiving a high protein diet secrete a juice especially rich in trypsin; on a high carbohydrate intake the pancreatic amylase concentration is greatly increased; on a high fat-low protein diet, however, the secretion of all enzymes is inhibited. It has been suggested that *carbonic anhydrase* is importantly related to the intracellular conversion of  $\text{CO}_2$  to  $\text{H}_2\text{CO}_3$  and hence to the formation of  $\text{HCO}_3^-$  for secretion.<sup>3</sup>

**Proteolytic Enzymes of Pancreatic Juice.** The major proteolytic enzymes of pancreatic juice appear to be (1) trypsin, (2) chymotrypsin, and (3) a carboxypolypeptidase, each of which has been obtained in crystalline form. The combined activities of these (and possibly other) enzymes was formerly believed to be due to a single enzyme which was called trypsin. This term is now, however, applied to a single enzyme in the group. As a class, these enzymes are similar in that they all catalyze the hydrolytic splitting of the peptide bond. They differ from one another in such respects as the type of peptide linkage required for activity; the type of activation from zymogen precursors, as discussed below; the pH optima, etc.

Trypsin and chymotrypsin may be classified as *endopeptidases* (Bergmann) acting on peptide linkages either in the central portion or the terminal portion of polypeptide chains. By the use of synthetic peptide substrates, Bergmann and Fruton found that trypsin acts on peptide linkages containing the carboxyl group of either lysine or arginine. Chymotrypsin on the other hand was found to act on peptide linkages involving the carboxyl group of tyrosine and phenylalanine. Thus the digestive action of trypsin and chymotrypsin on proteins appears to involve the splitting of specific types of peptide linkages in the molecule, the products of the action being, as with pepsin (see p. 364), either low-molecular-weight polypeptides or free amino acids, depending upon the location of the peptide linkages acted upon. There is some evidence of a synergistic action of these various endopeptidases; the action of one may uncover a linkage previously inaccessible to another.

Trypsin has its greatest activity at pH 8 to 9, the optimum pH depending somewhat on the nature of the substrate. It has some action in weakly acid solution. In acid solutions it resists temperatures near the boiling point, the denaturation that occurs being rapidly reversible on cooling. Trypsin is fairly stable in acidities as high as pH 2, but is digested by pepsin in acid solutions.

The carboxypolypeptidase activity of pancreatic juice is doubtless due to a mixture of enzymes, of which only one has been crystallized (Fig. 97). Carboxypolypeptidase is an example of an *exopeptidase*. It catalyzes the splitting of a peptide linkage involving the amino group of an amino acid whose carboxyl group is free, i.e., not combined in peptide linkage with another amino acid. The action of carboxypolypeptidase is thus

confined to the terminal portion of a polypeptide chain. If the free carboxyl group is blocked, as by the formation of an ester, the enzyme becomes ineffective. Carboxypolypeptidase has a pH optimum around 7.0.

**ACTIVATION OF TRYPSIN AND CHYMOTRYPSIN.** Pancreatic juice obtained from a fistula commonly shows no action on proteins. On entrance into the intestine the juice immediately becomes active. Apparently trypsin and chymotrypsin, as found in the pancreas and as secreted by that gland, exist not as such but as proenzymes called trypsinogen and chymotrypsinogen. These proenzymes have been obtained by Northrop and Kunitz

FIG. 97. CRYSTALLINE CARBOXYPOLYPEPTIDASE, PREPARED BY THE METHOD OF ANSON.

Courtesy, Dr. A. A. Plentl.

in crystalline form and show protein characteristics. Trypsin appears to be normally activated by the substance *enterokinase* secreted by the intestinal mucosa. Kunitz has clearly demonstrated that enterokinase acts on trypsinogen enzymatically. Furthermore it should be noted that crystalline trypsinogen (Fig. 98) can be activated by traces of trypsin, the activation increasing in rapidity as more active trypsin is formed. In less pure trypsin preparations activation appears to be slowed up by the presence of an inhibitor which has been obtained in crystalline form and appears to be a polypeptide. Strong salt solutions may also activate trypsin.

Chymotrypsinogen is apparently activated by active trypsin. Enterokinase thus does not activate chymotrypsinogen directly but indirectly through its action on trypsinogen.

**Pancreatic Amylase.** This is an amylolytic enzyme, or more probably a mixture of enzymes, which possesses somewhat greater digestive power than salivary amylase. As its name implies its activity is confined to the

starches and similar compounds, and the products of its amylolytic action are dextrins and, ultimately, maltose.

It is probable that the saliva as a digestive fluid is not absolutely essential. The salivary amylase is destroyed by the hydrochloric acid of the gastric juice and is therefore inactive when the chyme reaches the intestine. Should undigested starch be present at this point, however, it would be quickly transformed by the active pancreatic amylase. This enzyme is not present in the pancreatic juice of infants during the first few weeks of life, indicating that a starch diet is not normal for this period.

FIG. 98. TRYPSINOGEN CRYSTALS.

Courtesy, Dr. John H. Northrop.

Meyer and co-workers<sup>4</sup> have reported that pancreatic amylase appears to be identical with salivary amylase. They prepared crystalline amylases (see Fig. 74, p. 308) from hog pancreas, human pancreas, and human saliva, and compared them to ascertain whether enzymes of similar action from different glands of one species are more alike than corresponding enzymes from the same gland of different species. In all respects the two human amylase preparations were indistinguishable, and different from that of the hog pancreas.

Pancreatic amylase possesses protein properties. It requires ions such as  $\text{Cl}^-$  or  $\text{Br}^-$  for normal activity, and its optimal pH ranges from 6.3 to 7.2 in the presence of different neutral salts.

It has been shown that pancreatic amylase will digest raw starch. The raw starch of corn and wheat may be completely digested and absorbed by normal adults in amounts of more than 100 g. per day, whereas the raw potato starch is about 80 per cent available.

**Pancreatic Lipase.** This is a fat-splitting enzyme. It has the power of splitting the neutral fats of the food by hydrolysis, into fatty acid and glycerol. A typical reaction would be as follows:

<sup>4</sup> Meyer, Fischer, Bernfeld, and Duckert; *Arch. Biochem.*, 18, 203 (1948).

Pancreatic lipase is very unstable and is easily rendered inert by the action of acid. For this reason it is not possible to prepare an extract having a satisfactory fat-splitting power from a pancreas which has been removed from the organism for a sufficiently long time to have become acid in reaction.

Fodor<sup>5</sup> has reported that, in addition to lipase, hog pancreas contains a monovalent alcohol esterase. Although the different activities have not as yet been localized in separate protein fractions, the triglyceride-splitting activity is generally more resistant to heat, alkali, and trypsin than is the esterase activity.

Pancreatic lipase is undoubtedly the most important fat-splitting enzyme in the digestive tract. In the absence of pancreatic lipase, for example, when the pancreatic duct is obstructed by disease, the fat of the diet appears in the undigested form in the feces; this condition is known as steatorrhea. The enzyme is water-soluble and presumably a protein, although sufficiently pure preparations to prove this have not as yet been obtained, nor has the enzyme been crystallized. Its optimum pH is about 7. The action of the enzyme on fats is obviously dependent in large measure upon the surface of fat available; thus the more highly emulsified the fat is, the more surface is exposed to the aqueous phase containing the enzyme, and the more rapid is lipase action. Emulsification of fats in the digestive tract is facilitated by the presence of *bile*, because of the lowering of surface tension brought about by the bile salts (see Chapter 18). The bile also aids in fat digestion by facilitating removal of the end products of lipase action. It is believed by some that the bile actually activates pancreatic lipase; it appears more probable that the acceleration in lipase activity in the presence of bile is due to physiocochemical action by the bile salts in facilitating closer contact between the water-soluble lipase and the fat globule.

## PREPARATION OF AN ARTIFICIAL PANCREATIC JUICE

After removing the fat from the pancreas of a pig or sheep, finely divide the organ by means of scissors and grind it in a mortar. If convenient, the use of an ordinary meat chopper is a very satisfactory means of preparing the pancreas.

When finely divided as above, the pancreas should be placed in a 500-ml. flask, about 150 ml. of 30 per cent alcohol added, and the flask and contents shaken frequently for 24 hours. (What is the reaction of this alcoholic extract at the end of this period, and why?) Strain the alcoholic extract through cheesecloth, filter, nearly neutralize with potassium hydroxide solution, and then exactly neutralize it to litmus with 0.5 per cent sodium carbonate.

## PRODUCTS OF PANCREATIC DIGESTION OF PROTEIN

Into a 250-ml. flask introduce 20 g. of casein, 10 ml. of the artificial pancreatic juice prepared as described above, and 100 ml. of 1 per cent sodium carbonate. Allow to digest at 40° C. for 8 to 10 days with the addition of a few milliliters each of chloroform and toluene, the flask being stoppered with

<sup>5</sup> Fodor: *Arch. Biochem.*, 26, 307 (1950).

cotton. As the chloroform and toluene evaporate they must be renewed. Heat the mixture to boiling, and at the boiling point add acetic acid drop by drop until the mixture is acid in reaction. Cool and filter.

To 5 ml. of the filtrate add bromine water drop by drop. Note the development of a pink color which disappears in the presence of an excess of the reagent. This reaction indicates the presence of tryptophan.

To another 5-ml. portion of the filtrate add 10 drops of concentrated sulfuric acid and 10 ml. of a 10 per cent solution of mercuric sulfate in 5 per cent sulfuric acid. After mixing and allowing to stand for a few minutes, filter off the yellow precipitate which forms. This is an impure mercury compound of tryptophan.<sup>6</sup> Filter off the precipitate, reserving the filtrate, and wash the precipitate on the filter paper thoroughly with several small portions of water.

To small portions of the precipitate apply the Hopkins-Cole, xanthoproteic, and Millon tests. Tryptophan gives a positive reaction with the first two of these tests and is responsible for the Hopkins-Cole reaction as applied to protein.

Test portions of the filtrate from the mercuric precipitate by the Hopkins-Cole, xanthoproteic, and Millon reactions. Tyrosine responds to the latter two tests.

To the remainder of the original filtrate add a few drops of ammonia<sup>7</sup> (enough to make it slightly alkaline) and evaporate to a volume of 10 to 20 ml., using at first a free flame and completing the evaporation on a water bath. Transfer to a beaker and allow to stand for 1 or 2 days. Examine microscopically the crystals which separate out. Tyrosine crystallizes in sheaves of needles (see Fig. 44). Leucine forms small rosettes. Apply Mörner's reaction for tyrosine (see p. 138).

## GENERAL EXPERIMENTS ON PANCREATIC DIGESTION

### EXPERIMENTS ON TRYPSIN<sup>8</sup>

1. *The Most Favorable Reaction for Tryptic Digestion.* Prepare five tubes as follows:

- a. 3 ml. of neutral pancreatic extract + 3 ml. of water. pH 7.
- b. 3 ml. of neutral pancreatic extract + 3 ml. of water + 1 drop of phenolphthalein solution + 0.5 per cent  $\text{Na}_2\text{CO}_3$  to first faint pink color. pH 8.3.
- c. Same as (b) but add  $\text{Na}_2\text{CO}_3$  until the pink color no longer deepens. pH 10.
- d. 3 ml. of neutral pancreatic extract + 3 ml. of 2 per cent boric acid solution. pH 5.
- e. 3 ml. of neutral pancreatic extract + 3 ml. of 0.6 per cent HCl. pH 3.

Add a small piece of fibrin<sup>9</sup> to the contents of each tube and keep them at 40° C., noting the progress of digestion. In what reactions does trypsin act

<sup>6</sup> It has been claimed that a similar yellow precipitate forms in the presence of tyrosine, cystine, and polypeptides.

<sup>7</sup> If the solution is alkaline in reaction owing to the presence of fixed alkali while it is being concentrated, the amino acids will be broken down and ammonia will be liberated. Ammonia in slight excess does not cause such decomposition.

<sup>8</sup> For these experiments as well as for those on the other pancreatic enzymes commercial preparations of trypsin and pancreatin may be employed.

<sup>9</sup> Congo red fibrin (see Appendix) may be used in this and the following tests on tryptic digestion. If Congo red fibrin is used the experiments should be carried out at room temperature. Also in Exp. (b) and (c) phenolphthalein should not be added, but the proper amount of alkali as determined in a separate test. Buffer solutions of suitable pH may also be used in these tests instead of the acids and alkalies suggested.

and what is the optimum pH? How do the indications of the digestion of fibrin by trypsin differ from the indications of the digestion of fibrin by pepsin? Is the same degree of swelling of the protein noted?

**2. The Most Favorable Temperature.** (For this and the following series of experiments under tryptic digestion use the neutral extract plus an equal volume of 0.5 per cent sodium carbonate.) In each of four tubes place 5 ml. of alkaline pancreatic extract. Immerse one tube in ice water, keep a second at room temperature, and place a third in the incubator or water bath at 40° C. Boil the contents of the fourth for a few moments, then cool and also keep it at 40° C. Into each tube introduce a small piece of fibrin and note the progress of digestion. In which tube does the most rapid digestion occur? What is the reason?

**3. Demonstration of the Action of Enterokinase on Trypsin.**

a. PREPARATION OF ENTEROKINASE. Grind 5 g. of fresh duodenal mucosa of the hog with a little sand. Gradually add 50 ml. of water during the grinding process. Strain through cheesecloth.

A better preparation is made by drying the mucosa. From the upper three feet of the intestine of the hog scrape off the mucous membrane with a knife, or, better, a glass plate. Shake with three volumes of acetone. Let stand two hours. Filter. Wash the residue again with the same amount of acetone, then with a mixture of acetone and ether, and finally twice with ether. Dry in air and pulverize. A 1:50 extract of this powder in water may be used. The powder keeps indefinitely. The enterokinase may be further purified.

b. PREPARATION OF KINASE-FREE TRYPSIN SOLUTION. Immediately after killing the animal, grind hog pancreas in a meat chopper and dry with acetone and ether as in preparation of enterokinase (see above). Glycerol extracts of this dried pancreas (1:10) may be used. Kinase-free trypsin may also be further purified.

c. DEMONSTRATION OF ACTION OF ENTEROKINASE. Prepare five tubes as follows:

- (1) 2 ml. of pancreas extract + 5 ml. of water.
- (2) 2 ml. of pancreas extract + 1 ml. of duodenal extract + 4 ml. of water.
- (3) 1 ml. of duodenal extract + 6 ml. of water.
- (4) 2 ml. of pancreas extract + 1 ml. of duodenal extract + 4 ml. of water.
- (5) 2 ml. of pancreas extract + 1 ml. duodenal extract (boiled) + 4 ml. of water.

Boil contents of Tube 4 for 5 minutes and cool to 40° C. Keep all tubes at 40° for 20 minutes for activation. Add 1 ml. of 0.5 per cent sodium carbonate to each tube and the same quantity (about the size of a pea) of fresh fibrin. Shake the tubes and place at 40° C. Observe frequently during the course of an hour. Tube 2 should show the most rapid digestion. Why?

**4. Quantitative Determination of Tryptic Activity.**<sup>10</sup> See Spencer's Method, p. 390.

## EXPERIMENTS ON PANCREATIC AMYLASE

**1. Demonstration of Presence of Amylase in the Pancreas.** Into a test tube introduce 5 ml. of starch paste and 2 ml. of pancreatic extract. Shake and put in a water bath at 40° C. for 30 minutes. Divide into two parts. Test one with iodine for undigested starch and the other by Benedict's test for reduc-

<sup>10</sup> A number of proteolytic enzymes may be quantitatively determined by means of the fibrin-plate method. This procedure is both convenient and sensitive. Astrup and Alkjaersig: *Arch. Biochem. Bioph.*, 37, 99 (1952).

ing sugar. The reducing sugar formed by pancreatic amylase is maltose as is the case with salivary amylase.

**2. Quantitative Determination of Amylolytic Activity: Method of Willstätter, Waldschmidt-Leitz, and Hesse.** In this method the reducing sugar formed is determined by hypoiodite titration.

Into a 50-ml. cylinder (with a ground-in stopper) introduce 25 ml. of a freshly prepared 1 per cent solution of soluble starch (see the Appendix), 10 ml. of buffer solution pH 6.8 (5.1 ml. of 0.2 M  $\text{KH}_2\text{PO}_4$  + 4.9 ml. of 0.2 M  $\text{Na}_2\text{HPO}_4$ ), and 1 ml. of 0.2 N NaCl. Mix and bring to a temperature of 37° C. Add the enzyme solution to be tested. Mix and return at once to the bath. Keep at 37° C. for exactly ten minutes. Then add 2 ml. of N HCl to stop the action. Wash the contents of the cylinder with a little water into an Erlenmeyer flask. Add 0.6 ml. of 0.1 N iodine solution for each mg. of maltose expected. Then add drop by drop with shaking 0.1 N NaOH sufficient to neutralize the added HCl and to change the primary phosphate of the buffer to secondary form (for both of which 30 ml. is required) and a further amount 1.5 times the volume of the iodine solution used. Let stand 15 minutes, acidify with dilute  $\text{H}_2\text{SO}_4$ , and titrate the excess iodine with 0.1 N thiosulfate. The iodine taken up by the starch and the enzyme solution is found in a control determination. One ml. of 0.1 N I is equivalent to 17.15 mg. of  $\text{C}_{12}\text{H}_{22}\text{O}_{11}$  or maltose.

CALCULATION. The equation for a monomolecular reaction is

$$k = \frac{1}{t} \log \frac{a}{a - x}$$

Apply this formula to the determination above:  $a$  is the amount of substrate (not the full 0.25 g. of starch but 75 per cent of this, or 0.1875, as representing the practical limits of saccharification of the starch);  $t$  is the time (10 minutes). Assume the iodine required to be 2.29 ml. and the blank determination 0.53 ml. Then the iodine taken up by the maltose will be  $2.29 - 0.53 = 1.76$  ml. of 0.1 N I, equivalent to 0.0302 g. of maltose, and

$$k = \frac{1}{10} \log \frac{0.1875}{0.1875 - 0.0302} = 0.0076$$

This reaction constant expresses also the number of units of amylase in the amount of amylase preparation used. The unit of amylase is 100 times the amount required under the given conditions to give a constant of 0.01. This is approximately the amount in 2 cg. of dried pancreas. The amylolytic strength of a preparation may be expressed in units per cg. For plant amylase a buffer of pH 5 should be used. For accurate work the amount of enzyme used should be such as to give a constant of 0.01 — 0.03 or hydrolysis of not over 40 per cent of the substrate.

## EXPERIMENTS ON PANCREATIC LIPASE<sup>11</sup>

**1. Influence of Bile on Action of Lipase.** Prepare five test tubes as follows:

a. 0.5 ml. of olive oil + 5 ml. of neutral pancreatic extract + 4.5 ml. of water.

b. 0.5 ml. of olive oil + 9.5 ml. of water.

c. 0.5 ml. of olive oil + 8.5 ml. of water + 1 ml. of bile.

d. 0.5 ml. of olive oil + 5 ml. of neutral pancreatic extract + 3.5 ml. of water + 1 ml. of bile.

e. 5 ml. of neutral pancreatic extract + 4 ml. of water + 1 ml. of bile.

<sup>11</sup> A vegetable lipase preparation may be made as described on p. 331.

Shake the tubes thoroughly, add a drop of toluene to each, and place them in an incubator or water bath at 40° C. for 24 hours. At the end of this period add a drop of phenolphthalein to each tube and titrate with 0.05 N NaOH to a permanent pink color. Shake the tube during the titration. Record the amount of 0.05 N alkali necessary to neutralize the contents of each tube. Which tube required the most? Why?

2. *Litmus-milk Test.* Into each of two test tubes introduce 10 ml. of milk and a small amount of litmus solution.<sup>12</sup> To the contents of one tube add 3 ml. of neutral pancreatic extract<sup>13</sup> and to the contents of the other tube add 3 ml. of water or of boiled neutral pancreatic extract. Keep the tubes at 40° C. and note any changes which may occur. What is the result and how do you explain it?

3. *Copper Soap Test for Lipase.* Prepare a 2:100 agar-agar solution, mix with an equal volume of 5:100 starch paste, incorporate in this mass about 1/40 of its volume of the neutral fat desired (butter, lard, etc.), heat with constant agitation until a homogeneous emulsion is produced, pour into a Petri dish, and cool rapidly. With a fine pipet distribute on the surface of the solidified mass small drops of the liquid to be tested, keep 1 hour at 38° C., pour a saturated aqueous CuSO<sub>4</sub> solution over the surface, allow to stand 10 minutes, and rinse with H<sub>2</sub>O. The presence of lipase is shown by the appearance of beautiful bluish-green spots. These are copper soap. The addition of the starch, which is not indispensable, produces a rather white opaque background against which the spots appear very distinct.

4. *Ethyl Butyrate Test.* Into each of two test tubes introduce 4 ml. of water, 2 ml. of ethyl butyrate, C<sub>3</sub>H<sub>7</sub>COO·C<sub>2</sub>H<sub>5</sub>, and a small amount of litmus powder. To the contents of one tube add 4 ml. of neutral pancreatic extract and to the contents of the other tube add 4 ml. of water or of boiled neutral pancreatic extract. Keep the tubes at 40° C. and observe any change which may occur. What is the result and how do you explain it? Write the equation for the reaction which has taken place.

5. *Quantitative Estimation of Lipase: Method of Willstätter, Waldschmidt-Leitz, and Memmen.* A constant degree of activation is obtained by the addition of albumin and calcium salts. An adsorption compound fat-Ca oleate-albumin-lipase very favorable to lipase action is believed to be formed.

Into a wide-mouth 30-ml. flask with a ground glass stopper, introduce the enzyme preparation made up to 10 ml. with water, then 2.5 g. of olive oil and 2 ml. of buffer (0.66 ml. of N NH<sub>4</sub>OH + 1.34 ml. of N NH<sub>4</sub>Cl) and 0.5 ml. of 2 per cent CaCl<sub>2</sub>. Shake a little and add 0.5 ml. of 3 per cent albumin solution. Shake by hand uniformly and strongly for 3 minutes to get a stable characteristic emulsion. Put in a thermostat at 30° C. for 57 minutes (total time of lipase action 60 minutes). Wash into an Erlenmeyer flask with 96 per cent alcohol to make a volume of about 125 ml. Add 20 ml. of ether and mix. This stops lipase action. Add 12 drops of 1 per cent solution of thymolphthalein and titrate with 0.1 N alcoholic KOH to a distinct blue color. From the reading subtract the titration value of the buffer (13.4 ml. of 0.1 N KOH) and of the enzyme solution. A lipase unit is the amount required under the specified

<sup>12</sup> Litmus-milk powder may be used if desired. To prepare it add 1 part of powdered litmus to 50 parts of dried milk powder. For use in testing, 1 part of powdered litmus-milk may be added to 9 parts of water.

<sup>13</sup> Commercial *pancreatin* may be used in this test if desired.

conditions to split 24 per cent of 2.5 g. of olive oil of a saponification value of 185 (meaning that 1 g. of the olive oil completely hydrolyzed requires for neutralization 185 mg. of KOH).

CALCULATION. One ml. of 0.1 N KOH = 5.61 mg. of KOH. If 12.5 ml. of 0.1 N KOH (corrected for control) were required  $12.5 \times 5.61 = 70.6$  mg. of KOH. Then  $\frac{70.6 \times 100}{185 \times 2.5} = 15.1$  per cent split. If the splitting is more than 24 or less than 10 per cent, repeat. Ten per cent decomposition by pancreatic lipase corresponds to a lipase value of 0.028, and 24 per cent to 1.0. Add to 0.28 an amount of 0.044 for each per cent of decomposition above 10 and up to 24. If using other than pancreatic lipase or if other conditions are altered, a special curve of variations of percentage hydrolysis with different amounts of enzyme must be plotted from experimental data obtained using the enzyme in question. Concentration of lipase may be expressed as units per cg. of substance.

## Intestinal Digestion

The digestive processes carried out by the enzymes of the pancreatic juice occur within the lumen of the intestine. It is probable that peptic digestion also continues in the upper part of the duodenum until the acid chyme has been neutralized by the pancreatic and intestinal juices. However, we shall consider in this chapter only those digestive processes which are effected by enzymes secreted in the intestinal juice (*succus entericus*) and those present in the intestinal mucosa.

The intestinal juice is most abundant in the duodenum and jejunum and is of two types: (a) a secretion poor in enzyme content but rich in mucin which is produced periodically at about two-hour intervals, and (b) a digestive juice which is secreted in response to a meal, probably through mechanical stimulation of the intrinsic nerves of the intestine. A hormone *enterocrinin*, liberated by the mucosa in response to a meal, may be concerned in stimulation of the intestinal glands.

The reaction of the intestinal contents is influenced by the state of digestion and the relative volumes of acid chyme, pancreatic and intestinal juices, and bile present in any given segment of intestine. The reaction of the small-intestine contents is frequently acid, and the pH is usually considerably lower than that of the intestinal juice. *Intestinal secretions* collected at intervals from the jejunum through the colon contain about the same concentrations of cations, but progressively higher concentrations of bicarbonate and lower concentrations of chloride. Thus the intestinal secretions are more alkaline in the lower reaches of the intestine.

The enzymes of the intestine are of great importance, since their action, in some cases, supplements that of other digestive enzymes. They also serve to complete the digestive process by catalyzing the further hydrolysis of products of other digestive reactions. The enzymes include (1) *peptidases* (aminopolypeptidases and dipeptidases); (2) *carbohydrases* (sucrase, maltase, and lactase); (3) enzymes acting on nucleic acids, including a nonspecific *phosphatase*; (4) *lecithinase*. Some of these enzymes are not actually present in the intestinal juice, or occur there in only small amounts. Examples of such enzymes are lactase, nucleotidase, and nucleosidase. These enzymes evidently exert their action at the surface of the mucosal cells or intracellularly. These latter sites of action may also be important in the case of other intestinal enzymes.

**Peptidases.** AMINOPOLYPEPTIDASES. The aminopolypeptidases of the intestinal mucosa act on the products of peptic and tryptic digestion to

catalyze the splitting of the peptide linkage adjacent to the end of polypeptide chains bearing the free amino group. The products are a free amino acid and a polypeptide of lower molecular weight. These enzymes supplement the effect of carboxypolypeptidases of pancreatic juice which have their site of action at the carboxyl end of the polypeptide chain. Complete hydrolysis of polypeptides may be effected by aminopolypeptidases, since they slowly hydrolyze synthetic dipeptides; but this result is better accomplished by the dipeptidases. Some structural specificity is undoubtedly involved in aminopolypeptidase action; thus leucylpeptidase in hog intestinal juice is especially active in hydrolyzing peptides containing leucine as a terminal amino acid.

**DIPEPTIDASES.** The dipeptidases have relatively little action on polypeptides but split dipeptides rapidly.

The combined activity of aminopolypeptidases and dipeptidases was once attributed to a single enzyme called *erepsin*. This name is now used only as descriptive of the over-all results of these enzymes. *Ereptic enzymes* are found not only in intestinal mucosa but in other plant and animal tissues as well. None of these enzymes has been crystallized. Since the ereptic enzymes (and carboxypolypeptidase) act only on peptide linkages adjacent to the end of a polypeptide or peptide chain, they are referred to as *exopeptidases* to distinguish them from pepsin and the tryptic enzymes which act on centrally located peptide bonds. Through the combined action of all these enzymes, protein is finally hydrolyzed to individual amino acids.

**Carbohydases.** **SUCRASE.** The three carbohydases sucrase, maltase, and lactase are also important enzymes of the intestinal mucosa. The sucrase acts upon sucrose and inverts it with the formation of glucose and fructose. Sucrases may also be obtained from several vegetable sources. For investigational purposes sucrase is ordinarily obtained from yeast (see p. 331). Intestinal sucrase has an optimum pH of 5 to 7; yeast invertase acts best at pH 4.5.

**LACTASE.** This enzyme splits lactose with the consequent formation of glucose and galactose. Freshly prepared suspensions of intestinal mucosal tissue are much more active than water extracts, or the intestinal juice, indicating that the activity is intimately associated with the mucosal cells. The optimum pH for intestinal lactase is about 5.4 to 6.0.

**MALTASE.** This enzyme possesses the power of splitting maltose, the end product of the digestion of starch by amylase, into glucose. Maltase is best prepared from yeast. Its optimum pH is 6.7 to 7.2.

**Nucleases.** A *polynucleotidase* in intestinal juice results in the depolymerization and break up of nucleic acid to nucleotides. The nucleotides are then hydrolyzed by a *nucleotidase* (a phosphatase) to give purine and pyrimidine nucleosides and phosphoric acid. A *nucleosidase* decomposes the purine nucleosides to the purine base and ribose (or deoxyribose). The pyrimidine nucleosides are absorbed unchanged but are decomposed by enzymes found in other organs. The intestinal phosphatase responsible for the hydrolysis of the phosphoric acid ester linkage of nucleotides is nonspecific in its action, since it attacks other phosphoric acid ester substrates such as glycerophosphate and hexose phosphates. A part of the

alkaline phosphatase activity of normal plasma is due to the intestinal phosphatase which has entered the blood.

**Lecithinases.** Enzymes which hydrolyze lecithins to various products, depending upon the experimental conditions and time of action, are present in intestinal mucosa.

**Enterokinase.** This substance is discussed in Chapter 16. Though present in intestinal juice, it is not a digestive enzyme but activates the tryptic enzymes.

## GENERAL EXPERIMENTS ON INTESTINAL DIGESTION

*Preparation of Intestinal Extract.* Wash a piece of hog intestine about 18 inches long. Run it through a meat-chopper or, better, scrape off the mucosa with a knife or piece of glass. Rub in a mortar with sand. Add 5 volumes of water and a little chloroform and let stand at room temperature for 24 hours. If necessary to expedite laboratory work the extract may be used after two hours. Strain through cloth or loose cotton. This extract may be used for the general experiments on phosphatase, ereptic enzymes, and sucrase. The presence of some mucosal cells in suspension increases the enzyme activity.

### EXPERIMENT ON INTESTINAL PHOSPHATASE

*Demonstration of Action of Intestinal Phosphatase on Nucleic Acid and on Sodium Glycerophosphate.* Prepare a 2 per cent solution of yeast nucleic acid with the aid of just sufficient dilute NaOH to make the resulting solution pink to phenolphthalein (pH 8.6). Then prepare a 2 per cent solution of sodium glycerophosphate and make just pink to phenolphthalein. To each of four test tubes add 10 ml. of the intestinal extract prepared as above. Boil two—Tubes 2 and 4—for one to two minutes. To Tubes 1 and 2 then add 10 ml. of the 2 per cent nucleic acid solution and to tubes 3 and 4, 5 ml. of the glycerophosphate solution. Add 2 to 3 ml. each of toluene and chloroform to each mixture. Keep at 38° C. for 24 hours.

Heat the tubes to boiling in a water bath to coagulate protein. Add 5 ml. of 5 per cent HCl and allow to stand for one hour. This precipitates any unchanged nucleic acid. Filter and take aliquots of the filtrate (about 10 ml.). Precipitate the phosphate from each mixture by adding 5 ml. of magnesia mixture and 5 ml. of ammonia. Allow to stand over night. A heavy precipitate of magnesium ammonium phosphate should be found in Tubes 1 and 3, indicating that the phosphoric acid of the nucleic acid and of the glycerophosphate has been liberated by the phosphatase of the intestinal extract. The control should show only a slight precipitate.

### EXPERIMENTS ON PEPTIDASES

*1. Demonstration of Peptidase Activity.* To about 5 ml. of a 1 per cent solution of peptone in a test tube add about 10 ml. of the intestinal extract prepared as described above. Prepare a second tube containing a like amount of peptone solution, but boil the intestinal extract before introducing it. Place the two tubes at 38° C. for two to three days. At the end of that period heat the contents of each tube to boiling, filter, and try the biuret test on each filtrate. In making these tests, care should be taken to use like amounts of filtrate, sodium hydroxide, and copper sulfate in each test in order that the drawing of correct conclusions may be facilitated. The contents of the tube which contained the boiled extract should show a deep pink color with the biuret test, owing to the peptone still present. On the other hand, the biuret

test upon the contents of the tube containing the unboiled extract should be negative or exhibit, at the most, a faint pink or blue color, signifying that the peptone, through the influence of the intestinal extract, has been transformed, in great part at least, into simple peptides and amino acids which do not respond to the biuret test. To other portions of the filtrates add a few drops of bromine water. A violet color indicates free tryptophan and hence that amino acids have been liberated. Proteinase in the extract changes the peptone to polypeptides. The latter are broken down by aminopolypeptidase to simple peptides which under the action of dipeptidase yield amino acids. The action of several enzymes is thus involved.

**2. Demonstration of Dipeptidase Using Glycyltryptophan.** Introduce 5 ml. of glycyltryptophan solution into each of two tubes. To one add 5 ml. of intestinal extract, to the other 5 ml. of boiled extract. Let stand over night. Add a few drops of bromine water to each. A violet color indicates free tryptophan and hence the presence of dipeptidase.

**3. Quantitative Determination of Dipeptidase.** To 25 ml. of 0.05 N glycylglycine add NaOH to pH 8. Warm to 37° C. Add enzyme solution. Carry out a formol titration on an aliquot at once (control) and repeat at intervals. Choose a determination representing less than 30 per cent digestion. Calculate  $k$  in:  $k = (1/t) \cdot \log a/(a - x)$ . Activity equals  $k/g$ . enzyme preparation.

## EXPERIMENTS ON CARBOHYDRASES

**1. Demonstration of Sucrase.** To about 5 ml. of a 1 per cent solution of sucrose, in a test tube, add about 1 ml. of intestinal extract, prepared as described above, and a few drops of chloroform. Prepare a control tube in which the intestinal extract is boiled before being added to the sugar solution. Let stand for 24 hours. Heat the mixture to boiling to coagulate the protein material, filter, and test the filtrate by Benedict's test (see p. 66). The tube containing the boiled extract should give no response to Benedict's test, whereas the tube containing the unboiled extract should reduce the Benedict's solution. This reduction is due to the formation of glucose and fructose from the sucrose through the action of the enzyme sucrase which is present in the intestinal epithelium.

For the preparation of vegetable sucrase see p. 331.

**2. Demonstration of Lactase and Maltase.** Repeat the above experiment but use 1 per cent solutions of lactose and maltose. Is there any evidence of lactase and maltase activity?

## Bile and Liver Function

**Secretion of Bile.** The bile is secreted continuously by the liver and passes into the intestine through the common bile duct which opens near the pylorus. This process is continuous even during prolonged fasting, provided there is no obstruction. The ingestion of food, however, increases the secretion. Meat is effective in this respect, fat less so, and starch and sugar appear to be without effect.

Introduction of acid into the duodenum stimulates bile formation, suggesting that secretin is responsible. However, injection of secretin preparations, though leading to a copious secretion of pancreatic juice in one to three minutes, produces a much slighter secretion of bile and then only after seven to nine minutes. Ligation of the pancreatic vein prevents this action on the liver; hence it is suggested that some metabolic product of the pancreas is responsible.

Bile salts absorbed from the intestine have a marked power to stimulate bile formation. The passage of bile directly from the liver or through the emptying of the gallbladder serves to induce a further secretion. Dehydrocholic acid is an especially effective cholagogue.

**Mechanism of Emptying of the Gallbladder.** There appear to be at least two mechanisms active in gallbladder emptying. One of these involves the contraction of the gallbladder and the other the tone of the sphincter of Oddi at the entrance of the common bile duct into the intestine. Cream or egg yolk causes an emptying of the gallbladder apparently by inducing an active contraction of this organ, probably accompanied by a relaxation of the sphincter at the same time. The active agent is the free fatty acid liberated on digestion of these foods. The organic acids of fruits and the gastric acid have the same effect. In cases of acute cholecystitis, fats, acid fruits, and meats, which stimulate acid secretion in the stomach, should therefore be reduced in the diet in favor of cereal foods. The contraction is apparently brought about through liberation from the intestinal mucosa of a hormone, cholecystokinin, whose chemical nature is not yet determined. Magnesium sulfate promotes evacuation by causing a dilation of the sphincter.

**Functions of the Bile.** We may look upon the bile as an excretion as well as a secretion. In the fulfillment of its excretory function it passes such substances as lecithin, metallic compounds, cholesterol, and the decomposition products of hemoglobin into the intestine and in this way aids in removing them from the organism. As a secretion, the bile assists materially in the digestion and absorption of fats from the intestine by

its emulsifying action on the fats of the diet and by facilitating the absorption of the fatty acids formed by the action of the pancreatic juice. A decreased appetite for fats has been shown in rats after the ligation of the common bile duct. A further important function of the bile is to aid in the absorption of vitamin K. Symptoms of vitamin K deficiency frequently accompany the absence of an active secretion of bile into the intestine.

**Composition of Bile.** The bile is a ropy, viscid fluid which is alkaline in reaction (pH 7.8) when it issues from the liver, and ordinarily possesses a decidedly bitter taste. It varies in color in the different animals, the principal variation being yellow, brown, and green. Fresh human bile from the living organism ordinarily has a yellow-brown or golden-yellow color. Post-mortem bile is variable in color. It is very difficult to determine accurately the amount of normal bile secreted during any given period. For an adult man it has been variously estimated at from 500 ml. to 1100 ml. for 24 hours. The specific gravity of the bile varies between 1.010 and 1.040, and the freezing point is about  $-0.56^{\circ}\text{C}$ . As secreted by the liver, the bile is a clear, limpid fluid which contains a relatively low content of solid matter. This secretion has a specific gravity of approximately 1.010. After it reaches the gallbladder, however, it becomes mixed with mucous material from the walls of the gallbladder, and this process coupled with the continuous absorption of water and certain other components from the bile has a tendency to concentrate the secretion. Therefore the bile as we find it in the gallbladder ordinarily possesses a higher specific gravity than that of the freshly secreted fluid. The specific gravity under these conditions may run as high as 1.040. There is a decrease in inorganic salts owing to absorption, while the concentration increases the content of organic substances. Even though it is concentrated in the gallbladder, the bile remains practically isotonic with the blood because the increased content of high-molecular-weight bile salt ions is accompanied by a decrease in chloride and bicarbonate ions. The pH of bladder bile may fall as low as 6, as compared to the definitely alkaline reaction of fistula bile.

SELECTED ANALYSES ILLUSTRATING THE COMPOSITION  
OF HUMAN BILE  
(PARTS PER 1,000)

| <i>Constituent</i>      | <i>Fistula Bile</i> | <i>Bladder Bile</i> |
|-------------------------|---------------------|---------------------|

| Inorganic matter.....   | 7.4                 | 8.5                 |

The principal organic constituents of the bile are the salts of the bile acids, bile pigments, neutral fats, lecithin, phosphatides, nucleoprotein, mucin, and cholesterol. Inorganic constituents include chiefly sodium, chloride, and bicarbonate, some potassium, calcium, magnesium, and sulfate, and a trace of phosphate. The metals iron, copper, and zinc are also frequently present in detectable amounts. The bicarbonate content of hepatic bile is higher than that of serum; the chloride content of bile is lower than that of serum, the chloride ion being replaced largely by the organic bile salt ions.

The quantitative composition of bile varies according to the source of the bile, i.e., whether the bile for analysis is obtained from the gallbladder or by means of a fistula before it reaches the gallbladder. The difference in the composition of these two types of bile is shown in the table of selected analyses on p. 409.

**Bile Acids.** The bile acids are elaborated exclusively as far as is known by the hepatic cells of vertebrates. They may be divided into two groups: (1) the glycocholic acid group and (2) the taurocholic acid group. In human bile glycocholic acids predominate, while taurocholic acids are more abundant in the bile of carnivora. The glycocholic acids are combinations through peptide linkage of bile acids and *glycine*,  $\text{NH}_2\cdot\text{CH}_2\cdot\text{COOH}$ . The taurocholic acids are similar combinations of bile acids with *taurine*,  $\text{NH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{SO}_3\text{H}$ . Taurine is evidently derived in the body from cysteine.

There are several varieties of bile acids, and therefore there are several forms of glycocholic and of taurocholic acids, depending upon the nature of the bile acid entering into the combination. The principal bile acids are (1) cholic acid,  $\text{C}_{24}\text{H}_{40}\text{O}_5$ , with three hydroxyl groups; (2) deoxycholic acid,  $\text{C}_{24}\text{H}_{40}\text{O}_4$ , with two hydroxyl groups; (3) anthropodeoxycholic acid and (4) hyodeoxycholic acid which are isomeric with deoxycholic acid, differing only in the position of one hydroxyl group; and (5) lithocholic acid,  $\text{C}_{24}\text{H}_{40}\text{O}_3$ , which has a single hydroxyl group. Human bile contains the first three of these in the proportion of about three parts of cholic acid to one part of deoxycholic and some anthropodeoxycholic acid. Ox bile contains about 6 parts per 100 of cholic acid and about one-eighth as much deoxycholic acid. Hyodeoxycholic acid is found in hog bile and chenodeoxycholic acid (identical with anthropodeoxycholic acid) in the bile of the goose and chicken. The cholic acids are closely related in structure to cholesterol and are probably formed in the body from cholesterol or one of its immediate metabolic precursors. See the structural formulas for cholic and deoxycholic acids.

**Cholic acid (3,7,12-Trihydroxycholanic acid)**

**Deoxycholic acid (3,12-Dihydroxycholan-21-oic acid)**

The bile acids are present in the bile largely as sodium salts. The sodium glycocholate and taurocholate may be isolated in crystalline form, either as balls or rosettes of fine needles or in the form of prisms having ordinarily four or six sides (Fig. 99). The bile salts are readily soluble in water. The free acids are slightly soluble in water but readily soluble in alcohol.

The bile acids have the property of combining with fatty acids to form compounds which have been called choleic acids. These are coordination compounds, the molecules being joined through secondary valences. Fatty acids containing 16 or more carbon atoms combine with 8 molecules of bile acid; the lower fatty acids, with

**FIG. 99. BILE SALTS.**

from 6 to 1 molecule. These compounds are soluble and diffusible in alkaline or slightly acid solution. For this reason, and because they markedly lower the surface tension in solution and thus promote emulsification, the bile acids greatly assist in the digestion and absorption of fat in the intestines. Through similar combinations they likewise assist in the absorption of cholesterol, fat-soluble vitamins, carotene, and other substances. They are also responsible for holding the cholesterol of the bile in solution.

There is considerable evidence that the bile acids are used over and over again by the body. After secretion into the intestine, that fraction of the bile salts which is reabsorbed as choleic acid complexes is liberated in the intestinal mucosa. The bile salts set free, as well as any which have been absorbed as such, are carried to the liver in the portal circulation, where they become available for resecretion in the bile. This has been called the enterohepatic circulation of the bile salts. It is presumably responsible in part for the marked stimulatory (choleretic) power of the bile salts themselves over bile flow from the liver, since when the bile salts reach the liver they provide that organ with a readily available supply of a major constituent of the bile itself.

**Bile Pigments.** The pigments of normal bile are bilirubin and biliverdin (dehydrobilirubin). The green color predominating in certain biles

as ox bile is due to biliverdin. Other types of bile like human bile commonly show the yellowish-brown color of bilirubin (Fig. 100). Modifications of these pigments may be found in gallstones or in altered bile.

The bile pigments result mainly from the breakdown of the hemoglobin of the red cells; a consideration of the structures of the bile pigments (p. 413) indicates that they are derived specifically from the heme portion of hemoglobin (see Chapter 22). Other heme derivatives in the body—such as catalase, the cytochromes, etc.—may contribute to a certain extent to bile pigment formation. The formation of bile pigments has been shown to be a property of the cells of the reticuloendothelial system. Since these include the Kupffer cells lining the intralobular capillaries of the liver, a part of the bile pigments is produced in the liver. Other important sources are the spleen, lymph nodes, and bone marrow. Wherever extravasation of blood occurs, e.g., following bruises, a conversion of blood hemoglobin to bile pigment slowly takes place. This conversion is apparently going on even in normal red cells, since small amounts of bile pigment have been isolated from this source.

FIG. 100. BILIRUBIN. (OGDEN.)

The first step in the formation of bile pigments appears to involve an oxidative scission of the porphyrin ring, to produce carbon dioxide and an open-ring compound. In this process the iron is not necessarily lost from the molecule, nor does the open-ring compound lose its affinity for globin. One such compound of globin and an open-ring iron porphyrin derivative is called choleglobin, by analogy to hemoglobin; and other compounds analogous to those found in the field of heme chemistry are known. In general, these pigments are green in color (hence the names verdohemin, verdohemoglobin, verdohemochromogen, etc.) and the opening of the porphyrin ring has apparently rendered the iron labile, so that it is easily split off by such means as treatment with dilute acid. Further steps in bile-pigment formation are obscure; apparently the iron and the globin become detached in some way to produce biliverdin, which may then be reduced to form bilirubin.

Further stages in the transformation of bile pigments involve the action of intestinal bacteria. In the intestinal lumen, bilirubin undergoes reduction by bacterial action to form the substance mesobilirubinogen. This compound ordinarily is further reduced to form stercobilinogen, which on oxidation becomes converted into stercobilin, the principal pigment of normal feces. Stercobilin has been produced in the laboratory from mesobilirubinogen by incubation of the latter with normal feces, or with bile-free feces plus added bile. A portion of the stercobilinogen and stercobilin is apparently absorbed from the intestinal tract and re-excreted by the liver; thus some gets into the blood stream and ultimately is excreted by way of the kidneys into the urine. In the urine

these two pigments are known respectively as urobilinogen and urobilin. Considerable confusion has resulted from the nomenclature of these compounds; at the present time it appears to be largely a question of different names for the same substances. Normally the amounts of urobilinogen and urobilin in urine are rather small and obviously depend upon such factors as the rate of pigment production and reabsorption, and upon the efficiency of the liver in excreting the reabsorbed material. Thus the urobilinogen content of the urine will be low in simple anemias, but high in diseases associated with extensive blood destruction and where liver function is impaired.

The chemical relationship between certain of the various bile pigments and their derivatives is illustrated by the following structures: (Me = CH<sub>3</sub>; Et = C<sub>2</sub>H<sub>5</sub>; X = CH<sub>2</sub>·CH<sub>2</sub>·COOH).

Bilirubin is insoluble in water but its alkali salts are soluble. It is soluble in chloroform and somewhat in alcohol, but very slightly in ether or benzene. Biliverdin is insoluble in water, ether, or chloroform, but soluble in alcohol. The calcium salts of the pigments are insoluble in water. Solutions of bilirubin exhibit specific light absorption only at the extreme

blue end of the spectrum where the band merges into the end of the visible spectrum and is not ordinarily detectable as a discrete band in the spectroscope. If an ammoniacal solution of bilirubin-alkali in water is treated with a solution of zinc chloride, however, it shows an absorption spectrum similar to that of bilicyanin. When bilirubin is treated with diazotized sulfanilic acid, this reagent reacts with bilirubin to form a deeply colored azo dye, known as azobilirubin or azorubin. This reaction is the basis for the Van den Bergh test for bile pigments and is also used in the quantitative determination of bilirubin in biological fluids (see Chapter 23).

**Biliary Calculi (Biliary Concretions, Gallstones).** Biliary calculi, otherwise designated as biliary concretions or gallstones, are *frequently* formed in the gallbladder. These deposits may be divided into five classes, (1) cholesterol calculi, (2) cholesterol-calcium calculi, (3) cholesterol-calcium-pigment calculi, (4) calcium-pigment calculi, and (5) calculi made up almost entirely of inorganic material. This last class of calculus is formed principally of the carbonate and phosphate of calcium and is rarely found in man although quite common in cattle. The calcium-pigment calculus is also found in cattle, but is almost as rare in man as the inorganic calculus. This calcium-pigment calculus ordinarily consists principally of bilirubin in combination with calcium; biliverdin is sometimes present in small amount. The cholesterol calculus is the one found most frequently in man. Such calculi may be formed almost entirely of cholesterol, in which event their color is very light; or they may contain more or less pigment and inorganic matter mixed with the cholesterol, which tend to give calculi of various colors.

Our knowledge of the origin of gallstones is imperfect. Among the factors concerned may be stagnation of bile, disturbances of metabolism, and infection. Cholesterol is held in solution in bile by means of bile acids. If cholesterol excretion is increased or bile salt excretion diminished, cholesterol stones may form. Prolonged stagnation of bile may work in the same direction if the bile salt concentration is reduced by their resorption from the bladder. The resorption of alkaline bile salts tends also to decrease the pH of the bile and thus to reduce the solvent action of the bile salts on cholesterol, which is greater in alkaline than in acid solutions. Infection, with or without stagnation, provides abundant nuclei for stone formation, and chemical alterations in the bile favor the formation of cholesterol-calcium-pigment stones. The impairment in the concentrating power of the mucosa due to inflammation, through failure to keep the bile salt concentration sufficiently high, may also be a factor.

Okey<sup>1</sup> reports the finding of gallstones in guinea pigs being used for the study of effects of high cholesterol diets. The stones occurred only when cholesterol and riboflavin were added to diets containing 25 per cent protein, and were not found when the riboflavin concentration was decreased.

For a discussion of cholesterol see Chapter 11, Nervous Tissue.

<sup>1</sup> Okey: *Proc. Soc. Exptl. Biol. Med.*, **51**, 349 (1942).

EXPERIMENTS ON BILE<sup>2</sup>

1. *Reaction.* Test the reaction of fresh ox bile, using suitable indicator paper. What is the approximate pH of bile?

2. *Nucleoprotein and Bile Acids.* Acidify 5 ml. of bile with acetic acid, drop by drop. Note the formation of a precipitate of nucleoprotein and bile acids.

3. *Inorganic Constituents.* Evaporate 10 ml. of bile to dryness in an evaporating dish. Fuse the residue with an excess of sodium carbonate-potassium nitrate "fusion mixture."<sup>3</sup> Cool, extract with 10 ml. of water, and add sufficient concentrated nitric acid to make the extract slightly acid. Filter, and test the filtrate for chloride, sulfate, and phosphate (see Chapter 28).

4. *Preparation of Bilirubin from Bile.* 500 ml. of bile from surgical drainage patients or 50 ml. of post-mortem gallbladder bile (diluted two to three times) is allowed to stand for a few hours in the refrigerator, and the supernatant fluid decanted. This is diluted several times with water and 5 per cent barium chloride solution is added with stirring. If the precipitate of barium bilirubinate does not flocculate immediately, add a few drops of 10 per cent NaOH. When the precipitate settles, the supernatant fluid is siphoned off. The precipitate is poured on a filter, washed with water on the paper, dried, and pulverized in a mortar. The powder is extracted with warm alcohol, followed by ether and chloroform, and again air-dried. The precipitate is transferred to a 50-ml. centrifuge tube, moistened with 10 per cent sulfuric acid, and washed three times in a little absolute alcohol, centrifuging and pouring off the alcohol each time. The residue is twice treated in a flask with boiling chloroform and filtered, and the chloroform evaporated, avoiding overheating toward the end. The bilirubin so obtained is rubbed into glacial acetic acid and centrifuged, the acid drained off, and the procedure repeated; the residue is air-dried. It is redissolved in boiling chloroform, filtered, and evaporated to dryness. The final product (40 to 100 mg.) is brick red in color, free from ash, and quite stable.

5. *Tests for Bile Pigments.* Practically all of these tests for bile pigments are based on the oxidation of the pigment, by a variety of reagents, with the formation of colored derivatives, e.g., mesobilirubin (yellow), mesobiliverdin (green to blue), and mesobilicyanin (blue to violet).

a. *GMELIN'S TEST.* To about 5 ml. of concentrated nitric acid in a test tube, carefully add 2 to 3 ml. of diluted bile so that the two fluids do not mix. At the point of contact note the various colored rings: green, blue, violet, red, and reddish-yellow. Repeat this test with different dilutions of bile and observe its delicacy.

b. *ROSENBACH'S MODIFICATION OF GMELIN'S TEST.* Filter 5 ml. of diluted bile through a small filter paper. Introduce a drop of concentrated nitric acid into the cone of the paper and note the succession of colors as given in Gmelin's test.

c. *VAN DEN BERGH TEST.* To 5 ml. of diluted bile, add 2 ml. of freshly prepared Ehrlich's diazo reagent.<sup>4</sup> Compare with a control on water alone. In this re-

<sup>2</sup> For experiments on the function of bile salts which may be carried out in this connection see Chapter 19, Intestinal Absorption.

<sup>3</sup> See Appendix.

<sup>4</sup> See Appendix.

action an azo dye is formed by a coupling reaction of bilirubin with diazotized sulfanilic acid of the Ehrlich reagent. This reaction is the basis for qualitative and quantitative procedures for estimation of bile pigments in blood serum. A very sensitive test for bile pigment in urine is based on its coupling with *p*-nitrobenzene diazonium *p*-toluene sulfonate.

### 6. Tests for Bile Acids.

a. FURFURAL- $\text{H}_2\text{SO}_4$  TEST (MYLIUS'S MODIFICATION OF PETTENKOFER'S TEST). To approximately 5 ml. of diluted bile in a test tube add 3 drops of a very dilute (1:1000) aqueous solution of furfural:

Now run about 2 to 3 ml. of concentrated sulfuric acid carefully down the side of the tube and note the red ring at the point of contact. Upon shaking the

FIG. 101. CHOLESTEROL.

Courtesy, Dr. C. A. Bachhuber.

tube the whole solution is colored red. Keep the temperature of the solution below  $70^{\circ}\text{C}$ . by cooling in running water during the mixing.

b. FOAM TEST (VON UDRÁNSZKY). To 5 ml. of diluted bile in a test tube add 3 to 4 drops of a very dilute (1:1000) aqueous solution of furfural. Place the thumb over the top of the tube and shake the tube until a thick foam is formed. By means of a small pipet add 2 to 3 drops of concentrated sulfuric acid to the foam and note the dark-pink coloration produced.

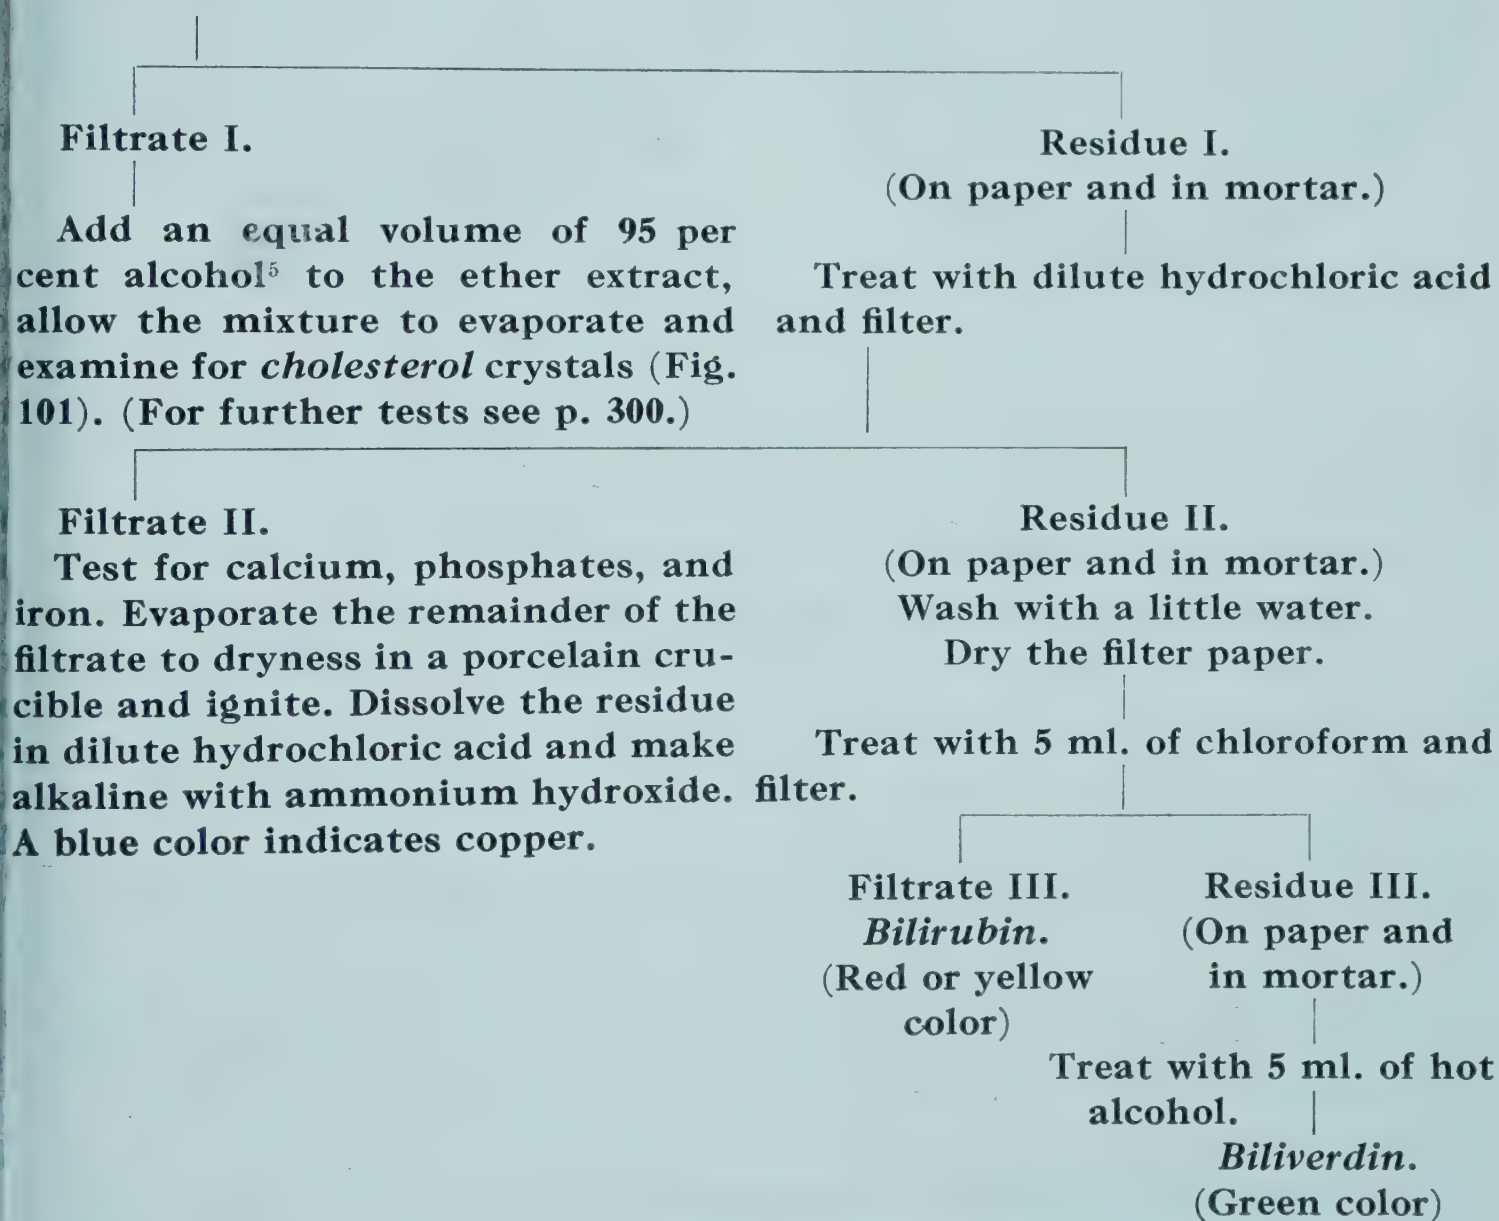

c. GREGORY AND PASCOE TEST. To 1 ml. of dilute bile solution add 6 ml. of 45 per cent  $\text{H}_2\text{SO}_4$  and 1 ml. of 0.3 per cent furfural solution. Stopper loosely and put in a water bath at  $65^{\circ}\text{C}$ . for 30 minutes. The presence of cholic acid is indicated by a blue color in the solution. This test may be used as a quantitative method.

d. **SURFACE TENSION TEST (HAY).** This test is based upon the property that bile acids have of lowering the surface tension of fluids in which they are contained. The test is performed as follows: Cool about 10 ml. of diluted bile in a test tube to 17° C. or lower and sprinkle a little finely pulverized sulfur upon the surface of the fluid. The presence of bile acids is indicated if the sulfur sinks to the bottom of the liquid. Prove this point by repeating the test with water instead of bile. Depending on the grade of sulfur used, this test indicates the lowering of the surface tension from 72 dynes/cm. for distilled water to values below 52–54 dynes/cm.

7. **Crystallization of Bile Salts.** To 25 ml. of undiluted bile in an evaporating dish add enough animal charcoal to form a paste, and evaporate to dryness on a water bath. Remove the residue, grind it in a mortar, and transfer it to a small flask. Add about 50 ml. of absolute alcohol and boil on a water bath for 20 minutes. Filter, and add ether to the filtrate until there is a slight permanent cloudiness. Cover the vessel and set it aside until crystallization is complete. Examine the crystals under the microscope and compare them with those shown in Fig. 99. Try one of the tests for bile acids upon some of the crystals.

8. **Analysis of Biliary Calculi.** Grind the calculus in a mortar with 10 ml. of ether. Filter.

9. **Preparation of Taurine.** Add 50 ml. of concentrated hydrochloric acid to 150 ml. of bile in a casserole. Boil the mixture in the hood down to a volume

<sup>5</sup> The alcohol is added because it is often found that crystallization from pure ether does not yield typical cholesterol crystals.

of about 50 ml., filter into a small evaporating dish to remove insoluble material, and concentrate the filtrate by boiling or on the water bath to a volume of about 10 ml. Filter the hot solution through a small filter into a 50-ml. graduated cylinder. If the volume is over 12 ml., return the filtrate to the evaporating dish, continue the evaporation, and filter a second time through the same filter. To the filtrate add 3 volumes of 95 per cent alcohol, mix, and cool in ice water for about 30 minutes. Filter off the crystals on a small funnel, allow to drain thoroughly, then transfer the crystals to a test tube and dissolve by warming in about 3 ml. of water. Add 5 volumes of alcohol and allow to stand until maximal crystallization has occurred. Filter

FIG. 102. TAURINE.

FIG. 103. GLYCINE. (SEE ALSO FIG. 38.)

off the pure crystals, wash with 5 ml. of alcohol, and allow to dry. Make the following tests upon the taurine just prepared:

*a.* Examine under the microscope. Compare with Fig. 102.

*b.* Solubility in water and alcohol.

*c.* Dissolve a little taurine in water and test this solution for sulfate by adding dilute hydrochloric acid and a few drops of barium chloride solution. Is any sulfate present? Boil the solution for a few minutes. Does taurine contain any ethereal sulfate (sulfate hydrolyzable by acid)? To another portion of taurine solution add sodium hydroxide, a few drops of lead acetate, and boil. Is any "lead-blackening" sulfur present?

*d.* Fuse a little taurine in a porcelain crucible with sodium carbonate-potassium nitrate "fusion mixture."<sup>6</sup> When the crucible contents are colorless, cool, dissolve carefully by the addition of dilute hydrochloric acid, filter into a test tube, and add barium chloride solution. What happens? Explain. What do these experiments indicate concerning the nature of the sulfur in taurine?

**10. Preparation of Glycine.** Concentrate the first alcoholic filtrate from Exp. 9 until no more alcohol remains. The glycine is present here in the form of a hydrochloride and may be liberated from this combination by the addition of freshly precipitated lead hydroxide or by lead hydroxide solution. Remove the lead from the filtrate by treatment with hydrogen sulfide. Filter

<sup>6</sup> See Appendix.

and decolorize the filtrate by animal charcoal. Filter again, concentrate the filtrate, and set aside for crystallization. Glycine separates as colorless crystals (Fig. 103). See also pp. 131 and 132.

## CHEMICAL EVALUATION OF THE FUNCTIONS OF THE LIVER

Many of the metabolic activities of the body are centered in the liver. Before discussing certain of these functions and the means for studying them in relation to liver disease, a résumé of the anatomy of the liver seems appropriate. It is necessary also to describe the major diseases of the liver in order to define more clearly the circumstances in which various chemical studies may be made and the response which may be expected.

The liver of a healthy adult may weight between 850 and 2600 g., with an average value of about 1600 g. Grossly, the liver consists of lobes varying in size and differing to some extent in the sources of afferent blood supplies. Each lobe contains a treelike framework of connective tissue which supports the parenchymal cells, blood vessels, and bile ducts. In its finer structure the liver consists of lobules, 1 to 2 mm. in diameter, composed of many secretory tubules formed by parenchymal cells surrounding a bile canaliculus. Blood reaches the lobules from the portal vein and the hepatic artery. The blood enters the sinusoids, spaces between cords or sheets of hepatic cells, and passes through them to drain into the central vein of the lobule.

The parenchymal cells, the most abundant and characteristic cells in the liver, are arranged so that each cell faces both a duct and a sinusoid containing blood, and have secretory and metabolic functions. Furthermore the secretory functions may be both exocrine and endocrine. In addition to the parenchymal cells, the liver contains large numbers of reticuloendothelial (Kupffer) cells which form a lining for the sinusoids. The Kupffer cells have phagocytic properties and are important in connection with hemoglobin breakdown and perhaps in immunity reactions.

## DISEASES OF THE LIVER AND BILIARY TRACT

Disturbances of metabolism occurring in liver disease are largely the result of failure of the parenchymal cells to carry out vital functions, because of (1) infections or noxious agents; (2) decreased mass of functioning cells; (3) decreased blood supply; (4) impaired nutrition; and (5) reaction of other organs to liver damage, e.g., brain, kidney, pancreas, adrenal, gonads, and spleen.

Infectious disease of the liver, such as viral hepatitis, is characterized by degeneration and necrosis of parenchymal cells, and may be followed by complete disappearance of cells and destruction of the normal architecture of the lobule. However, regeneration of the parenchymal cells can occur rapidly, and may produce an astonishingly large mass of cells within as little as 24 to 48 hours. Formerly, viral hepatitis was often mistaken for a disease of the bile ducts and the term "catarrhal jaundice" in the older literature is a result of this confusion.

Deposition of fat in the liver may occur from overnutrition, from dietary deficiencies, or from the action of toxic substances. Though fatty

liver resulting from overnutrition has little importance, deposition of fat caused by toxic substances is evidence of a serious disturbance of hepatocellular function. Among the nutritional deficiencies associated with fatty liver are those related to lack of betaine, choline, methionine, or other extrinsic sources of methyl groups. Low protein intake may also contribute to the production of fatty livers. Liver disease of purely nutritional origin is uncommon in the United States.

Liver damage may occur as a result of severe strains on metabolism associated with various other diseases, such as infectious mononucleosis, malaria, lobar pneumonia, typhoid fever, various anemias, syphilis, cholera, diabetes, and thyrotoxicosis.

Proliferation of the connective tissue of the liver may be of infectious, nutritional, toxic, hypoxic, or neoplastic etiology, or it may occur spontaneously because of diminished blood supply resulting from circulatory and other factors. The overgrowth of connective tissue in turn leads to disorganization of the liver structure and this again to further interference with the blood supply. The end result is a shrunken liver consisting largely of connective tissue and with a markedly decreased mass of parenchymal, reticuloendothelial, and vascular tissue. The designations portal cirrhosis, atrophic cirrhosis, and Laennec's cirrhosis have been used at various times to denote such scarred livers, although not all scarred livers conform to the pathologists' definition of Laennec's cirrhosis, which accounts for a large proportion of the liver disease seen in American hospitals. A less common form of cirrhosis, known as biliary cirrhosis, is found after prolonged biliary obstruction.

Obstruction of the bile ducts often causes jaundice which may be attributed erroneously to liver disease. It is essential to distinguish jaundice due to biliary obstruction from that caused by liver disease or excessive destruction of blood. Gallstones entering the common bile duct are the usual cause of biliary obstruction. Other causes include neoplastic disease of the ducts and carcinoma of the head of the pancreas. Stricture of the ducts may follow infection, surgical exploration, or other trauma. Disease of the gall bladder frequently is complicated by liver damage. The pancreas often shows evidence of being involved. Failure to establish the presence of biliary obstruction and to correct it may lead eventually to biliary cirrhosis.

Damage to the liver may be caused by a large number of chemicals and drugs. Carbon tetrachloride has been extensively used for production of experimental liver damage, and probably has been involved more often than realized as an insidious cause of clinical liver disease. Atophan, various sulfonamides, *p*-aminobenzoate, testosterone, arsenicals, and other drugs have been implicated. The effect on liver function, as measured by laboratory studies, resembles that observed in biliary obstruction rather than parenchymal liver disease.

Liver disease may affect the metabolism and functions of other organs, notably the brain and the kidneys. Impairment of kidney function commonly accompanies liver disease and may become a grave problem. The coexistence of hepatic and renal failure is often referred to as the *hepato-renal syndrome*.

THE CHEMICAL PHYSIOLOGY OF LIVER DISEASE<sup>7</sup>

**Carbohydrate Metabolism and Liver Disease.** The vital importance of the liver for maintenance of the blood glucose concentration is well established. Although hypoglycemia is not a common complication in patients suffering from acute parenchymal liver disease, it occurs in cirrhosis of the Laennec type with sufficient frequency to require that fasting blood glucose determinations be included in the study of such patients. Blood sugar concentrations as low as 25 mg. per 100 ml. are not uncommon. Glucose administered to patients with liver disease often causes a greater and more persistent rise in blood glucose than it does in healthy individuals; however, these findings are not of sufficient consistency to permit application as diagnostic or functional tests.

Decreased utilization of galactose in liver disease has provided the basis for one of the earlier tests of liver function.<sup>8</sup> The measurement of galactose excretion in urine originally used has been replaced by measurement of blood galactose concentrations.<sup>9</sup> An intravenous galactose-tolerance test has also been described,<sup>10</sup> by which the quantity of galactose removed per minute was found to be markedly decreased in liver disease.

**Serum Cholesterol and Lipides in Liver Disease.** The liver is the principal organ concerned with the metabolism and excretion of cholesterol. The serum lipides often show marked changes in diseases of the liver and biliary tract. Although serum cholesterol concentration and the partition between free and esterified cholesterol (see p. 580) is most frequently studied, neutral fat and especially phospholipide may also show marked changes. Relationships between free and esterified cholesterol and between free cholesterol and phospholipide which in health are maintained within narrow limits are subject to striking disturbances in severe parenchymal liver disease, where lipide concentrations often fall below the minimal levels observed in normal individuals of the same age. In viral hepatitis both the concentration of esterified cholesterol and the percentage of the total cholesterol esterified are lowered; if liver damage is severe, esterified cholesterol may become undetectable. Recovery is accompanied by rising concentrations of the esterified cholesterol in serum.

Cirrhosis of the Laennec type is also characterized by low serum lipide concentrations, especially when atrophy of the liver is extensive. Serum cholesterol concentrations of less than 100 mg. per 100 ml. are quite common. The proportion of esterified cholesterol also is lowered, although exceptions exist. Low phospholipide concentrations also are the rule.

Biliary obstruction regardless of cause is characterized by elevated concentrations of serum lipides. Extremely high concentrations, among the highest known to occur due to any cause, are encountered in patients with biliary obstruction of long duration or with biliary cirrhosis.<sup>11</sup> The

<sup>7</sup> For a detailed review, see Knisely, M. H., in *Trans. 10th Conference on Liver Injury*, edited by F. W. Hoffbauer, New York, Josiah Macy, Jr. Foundation, 1951.

reason is not known, since the bile does not appear to be an important route of lipide excretion.

Some use is made of serum cholesterol analyses for differentiation of primarily parenchymal lesions from primarily biliary lesions in jaundiced patients. However, such analyses offer little information that cannot be obtained more easily and dependably by other methods. The finding of low concentrations and ratios of esterified to total cholesterol in a jaundiced patient is strong but not conclusive evidence for parenchymal liver involvement of severe degree. Esterified cholesterol measurements have their greatest usefulness where the more sensitive tests become maximally positive and there is still a substantial amount of functioning parenchymal tissue remaining. As an indication for determination of esterified cholesterol, the presence of jaundice or of a marked elevation of serum bilirubin serves reasonably well.

Information concerning bile acids in liver disease is scanty and unsatisfactory. Improvements in sensitivity of the methods for bile acid determination in serum and bile should overcome this deficiency. Methods available in the past for estimating bile acid concentrations in serum indicated that bile acid enters the blood stream to attain concentrations of 10 to 20 mg. per 100 ml. in the presence of biliary obstruction. Elevated values may occur also in liver disease affecting the parenchyma predominantly.<sup>12</sup>

**Nitrogen Metabolism in Liver Disease.** The metabolic transformation of amino acids in the liver by synthesis, transamination, etc. may be impaired by disease or injury to produce an abnormal pattern of amino acid content in the blood and urine.<sup>13</sup> Certain tests employed for the study of liver function have as their basis the impaired metabolism of amino acids; for example, the tyrosine-tolerance test of Bernhart and Schneider,<sup>14</sup> and, in its possible relation to glycine synthesis, the well-known hippuric acid test of Quick (see p. 915) may also be included here. Amino acids contribute to the characteristic elevation of blood non-protein nitrogen content found in severe liver disease, along with urea, creatine, creatinine, uric acid, and ammonia, although the elevated blood NPN is mainly the result of impaired kidney function. Blood urea may not be elevated in proportion to creatinine and total NPN levels, possibly due to impairment of reactions involved in the synthesis of urea. Elevated creatine content is not entirely the result of renal failure. Interest in blood ammonia in liver disease has been revived by the finding of signs suggesting hepatic coma in patients suffering from cirrhosis who had received ammonia-containing ion-exchange resins.<sup>15</sup>

**Plasma Proteins in Liver Disease.** The liver has a dominant role in plasma protein synthesis, being the source of plasma albumin and fibrinogen (and probably other proteins associated with blood clotting) and contributing important components of the  $\alpha$ - and  $\beta$ -globulin fractions. The liver is also involved in the synthesis of  $\gamma$ -globulins, although

<sup>12</sup> Sherlock and Walshe: *Clin. Science*, **6**, 223 (1948).

<sup>13</sup> Dunn, Akawaie, Yeh, and Martin: *J. Clin. Invest.*, **29**, 302 (1950).

<sup>14</sup> Bernhart and Schneider: *Am. J. Med. Sci.*, **205**, 606 (1943).

<sup>15</sup> Gabudza, Phillips, and Davidson: *N. Eng. J. Med.*, **246**, 124 (1952).

there is much evidence indicating that  $\gamma$ -globulin synthesis is largely extrahepatic.

The serum albumin level is lowered in cirrhosis, in viral hepatitis during its clinically active stages, in nutritional liver disease, and in neoplastic disease involving the liver. Many consider determination of serum albumin to be among the most dependable measurements available for establishing the presence of liver disease (numerous other causes of low albumin concentration usually can be excluded without difficulty) and for following its clinical course. For this purpose it is superior to total serum protein concentration because changes in albumin are commonly masked by an equal and simultaneous rise in globulin, so that total protein may remain unchanged or nearly so. The lowered concentration of serum albumin is one of the major factors responsible for the occurrence of flocculation in the cephalin-cholesterol flocculation and related tests.

An increase in  $\gamma$ -globulin accounts for much of the increase in total globulin of serum. Whereas in healthy individuals the  $\gamma$ -globulin content rarely exceeds 1.6 g. per 100 ml., in liver disease concentrations double this are common, and concentrations five or more times the maximal normal occur in some patients with hepatitis. The marked rise in  $\gamma$ -globulin occurring in liver disease is similar to that occurring in many other diseases, and may therefore be somewhat nonspecific. In many patients it is accompanied by an elevation in the level of  $\beta$ -globulin, associated with the appearance of electrophoretically abnormal components in both  $\beta$  and  $\gamma$  fractions.

Fibrinogen appears to remain within normal limits or to be decreased in liver disease; the  $\alpha$ -globulin fraction also shows a tendency toward lower levels. This is particularly evident where some of the specific proteins included in this fraction are examined; for example, serum cholinesterase content is markedly decreased in many patients with liver disease, as may also be amylase, lipase, and esterase activities.

Of the procedures available for the study of liver disease which are based upon abnormality in plasma protein production or composition, the determination of plasma albumin and globulin levels are among the most useful. These methods are described in pp. 601 to 607. Some patients, especially those with liver damage of moderate degree, do not show significant change in serum albumin or total globulin concentrations. The quantitative measurement of  $\gamma$ -globulin concentration may offer some advantage in this connection and salting-out methods are available for this purpose. In addition, widely used methods for detecting changes in serum proteins of the type occurring in liver disease are the semiempirical flocculation and turbidity tests (see p. 595). For information concerning tests of this type and an analysis of their mechanisms, Saifer's review<sup>16</sup> may be consulted.

**Measurement of Excretory Capacity of the Liver.** Many substances, among them a number of dyes, are taken up by the liver and secreted into the bile with great rapidity. It has been found that in liver disease the rate of excretion may be lowered, and because of this the

<sup>16</sup> Saifer: *Am. J. Med.*, 13, 730 (1952).

use of certain of these substances has been of great value in the measurement of liver function. Disodium phenoltetrabromophthalein sulfonate (sulfobromophthalein, sodium; bromsulfalein), introduced in 1925 by Rosenthal and White, has proved to be superior to numerous other substances tested for this purpose. The procedure for the bromsulfalein test for liver function is given on p. 598.

**Detoxification Reactions of the Liver.** Numerous studies have demonstrated that in liver disease various reactions associated with detoxification are impaired. Among these are included the synthesis of hippuric acid following administration of benzoate. This is discussed in detail on p. 915. An improved test employing *p*-aminobenzoate and based upon serum analysis rather than on urinary excretion has been described.<sup>17</sup> Conjugation of various substances with glucuronic acid has also been used as a basis for liver-function tests.<sup>18</sup>

**Bile Pigment Metabolism in Liver Disease.** Jaundice is such a conspicuous sign of liver damage or bile-duct blockage that it has attracted more than its share of attention, often to the neglect of other and more important aspects of liver or biliary-tract disease. The chemistry and metabolism of the bile pigments is discussed on p. 411. Methods for the determination of bile-pigment levels in serum (icteric index, Van den Bergh test, total serum bilirubin) are described on pp. 590 to 595, along with the interpretation of results in relation to liver disease. In general, rising serum bilirubin levels have unfavorable implications; falling values are characteristic of remission of liver disease or biliary obstruction. In the urine, bilirubin is normally present in such low concentrations as to be undetectable by ordinary methods; the presence of detectable amounts of bilirubin in urine is indicative of liver damage or biliary obstruction, particularly in the early stage of disease. After the presence of the disease has been established, urine bilirubin tests offer little useful information. The detection of bilirubin in urine is described on p. 836.

Bilirubin excreted into the intestinal canal is reduced in part to form urobilinogen, which may then be reabsorbed into the blood and again excreted through the bile and also into the urine. Normal urine contains detectable amounts of urobilinogen (see p. 813); impaired excretory ability of the liver leads to an increased urinary output unless liver damage is such that secretion is suppressed, or there is biliary obstruction. Increased urobilinogen in the urine is a characteristic finding in parenchymal liver disease. In the feces, urobilinogen (stercobilin) levels are increased in hemolytic anemia and lowered in biliary obstruction.

A summary of the relation between liver disease, bile-pigment metabolism, and other aspects of liver function is found in the accompanying table.

**Other Chemical Manifestations of Liver Disease.** Abnormalities in blood clotting in liver disease result from a combination of defects, including diminished prothrombin and accelerator globulin levels and

## COMPARISON OF LIVER FUNCTION TESTS IN LIVER DISEASE

| <i>Syndrome</i>                             | <i>Bilirubin</i>                                                                                                                                                                   | <i>Tests for Parenchymal Involvement*</i>                                               | <i>Tests for Biliary Tract Involvement</i>                                                 |
|---------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------|
| Viral hepatitis without jaundice            | May be present in urine, and may increase slightly in serum. Urobilinogen may increase in urine.                                                                                   | BSF usually abnormal. CCF, TT, TF, one or more may be abnormal.                         | Normal                                                                                     |
| Viral hepatitis with jaundice               | Increased in serum and urine. Urobilinogen generally increased in urine and feces but may be absent.                                                                               | Abnormal                                                                                | Mainly normal but may be abnormal.                                                         |
| "Toxic" hepatitis; cholangiolitic jaundice  | Increased in serum and urine.                                                                                                                                                      | CCF, TT, TF, may be normal or abnormal; A/G usually normal.                             | Increased serum phosphatase, lipide. Similar to extrahepatic obstruction.                  |
| Laennec's cirrhosis                         | May or may not be abnormal in serum and urine. Urobilinogen variable.                                                                                                              | BSF abnormal. CCF, TT, TF abnormal in about $\frac{3}{4}$ of the cases. A/G abnormal.   | Variable. Phosphatase may be high.                                                         |
| Extrahepatic obstruction.<br><i>Partial</i> | Variable. Intermittent or continuous elevation.                                                                                                                                    | Generally normal, but liver parenchyma may become injured and tests positive.           | Variable with elevated serum phosphatase and lipide prevalent. Good response to vitamin K. |
| <i>Complete</i>                             | Extreme elevation. Very low fecal urobilinogen.                                                                                                                                    | Same as preceding.                                                                      | Elevated serum phosphatase and lipide. Good response to vitamin K.                         |
| Primary biliary cirrhosis                   | Bilirubin elevated. Urobilinogen variable.                                                                                                                                         | BSF increased. A/G abnormal. TT increased. CCF increased in $\frac{1}{2}$ of the cases. | Elevated phosphatase. Marked elevation of serum lipide, especially phospholipide.          |
| Hemolytic jaundice                          | Total serum bilirubin moderately elevated; direct bilirubin normal or slightly increased. Urine bilirubin negative. Feces urobilinogen increased, urine urobilinogen often normal. | Seldom abnormal but may become so due to hypoxia or other complications.                | Seldom abnormal. Pigment stones may cause biliary obstruction.                             |

\* Abbreviations: BSF, bromsulfalein; A, serum albumin; G, serum globulin; CCF, cephalin-cholesterol flocculation; TF, thymol flocculation; TT, thymol turbidity.

probably other factors.<sup>19</sup> The depletion of prothrombin in biliary obstruction is related to impaired vitamin K administration provided liver damage is not excessive. The evaluation of the clotting function of the blood is discussed in Chapter 22.

Liver disease may be associated with changes in blood and urine levels of such substances as citrate,<sup>20</sup> lactate, pyruvate, succinate, etc., but study of such changes has not yet reached the stage of general clinical application. Hormone metabolism may also be altered in liver disease; for example, both the conjugation of injected testosterone<sup>21</sup> and its excretion as 17-ketosteroid<sup>22</sup> are decreased in liver disease.

Disturbances of water and electrolyte balance are among the more significant and troublesome complications of liver disease. These are due in part to impairment of liver function and in part to the effect of liver disease on the kidneys and other organs. Among the blood analyses which are of clinical importance under these conditions are those for plasma proteins (p. 601), serum sodium (p. 649), and serum potassium (p. 652). Serum iron levels may also be altered in liver disease, being elevated in hepatitis<sup>23</sup> and in hemochromatosis; in the latter condition, the iron-binding capacity of the serum may be at the saturation level as compared with 14 to 69 per cent of capacity in cirrhosis and 28 to 59 per cent of capacity in normal individuals.<sup>24</sup>

Measurement of the alkaline phosphatase activity of serum (see p. 635) often assists in the differentiation of parenchymal liver disease from that due to obstruction and other lesions of the biliary tract. Biliary obstruction is characterized by a persistent increase in phosphatase activity to two or more times the maximum found in healthy individuals. This rise occurs regardless of the nature of the obstruction, whether due to calculus, stricture, or neoplasm. Elevation of serum alkaline phosphatase may provide one of the few clues to the presence of neoplastic growth in the liver.<sup>25</sup>

Elevated values are also found in toxic hepatitis of chemical origin, and in inflammatory disease of the bile ducts (cholangiolitic hepatitis), but are uncommon in cirrhosis of the Laennec type. The factors responsible for variation in serum phosphatase activity in liver disease are not clearly understood.

Serum cholinesterase activity (p. 638) is usually lowered in the presence of atrophy of or damage to the liver parenchyma, although not consistently. Serial measurement of cholinesterase activity appears to provide a useful method for following the course of liver disease, particularly that associated with deficient diets.

**Selection of Procedures.** The choice of methods for the study of disease of the liver or biliary tract will vary according to the type of information sought. The following outline shows the principal purposes for which chemical methods are applied together with a list of the pro-

cedures most likely to prove useful. A decision regarding the number of tests to be used requires experience and judgment. Usually those tests italicized will suffice for an initial study. To apply simultaneously the entire group of tests listed in any of the categories would seldom be justified.

1. Detection of liver damage in absence of jaundice, e.g., early or sub-clinical hepatitis: *urine bilirubin, bromsulfalein retention, direct and total serum bilirubin, flocculation tests (e.g., cephalin-cholesterol flocculation, thymol turbidity and flocculation), urine urobilinogen.*

2. Detection of residual liver damage, "recovery" stages of hepatitis, chronic hepatitis, chronic passive congestion, portal cirrhosis: *bromsulfalein, direct and total serum bilirubin, flocculation tests, serum albumin and globulin, prothrombin, serum cholinesterase, urine urobilinogen, and coproporphyrin.*

3. Following the course of the jaundiced patient suffering from parenchymatous disease; *direct and total serum bilirubin, flocculation tests, serum albumin and globulin, prothrombin.* In addition, if severe, *serum esterified cholesterol, cholinesterase.*

4. Differentiation of jaundice due to biliary disease from that due to parenchymatous disease: *serum alkaline phosphatase, cephalin-cholesterol flocculation and thymol turbidity, galactose tolerance, prothrombin, feces urobilinogen.*

5. Differentiation of extrahepatic biliary obstruction due to calculus from that due to neoplasm, stricture, etc.: *feces urobilinogen.*

6. For following the course of the surgical patient with disease of the biliary tract: *plasma prothrombin, phosphatase, direct and total serum bilirubin, albumin and globulin, electrolytes, blood urea N or NPN, serum lipides.*

7. Differentiation of hemolytic jaundice: *direct and total serum bilirubin, feces urobilinogen, erythrocyte fragility, reticulocyte count.*

## Intestinal Absorption

**Mechanism of Absorption.** Absorption is primarily a function of the small intestine. Very little absorption takes place from the stomach, and the process is nearly complete before the colon is reached. The small intestine is particularly adapted to carrying on this process by virtue of its great length (about 9 meters in man) and by the structure of its mucous membrane. The surface of the latter is greatly increased (to a total area of about 10 square meters) by the presence of folds and of fingerlike processes called villi. The latter possess a rich blood supply, lymph spaces called lacteals, and muscle fibers whose contractions mechanically assist absorption. The mucous membrane through which substances must pass to enter the blood or lymph is extremely thin, but it must not be forgotten that it consists of living cells.

Substances in solution tend to distribute themselves uniformly throughout the solvent, and this tendency, which we measure as osmotic pressure, is a powerful force. Undoubtedly osmosis may play some role in the absorption of certain substances which may be present in the intestine in far higher concentrations than in the blood. There is much evidence, however, that the process is rarely one of simple diffusion.

The facts with regard to the absorption of ionic substances (salts, amino acids, etc.) have been made much more intelligible by the development of the Donnan theory of membrane equilibria. This explains how it is possible for ionic diffusion to be more or less selective and how certain ions may pass into the blood although present there in higher concentration than in the intestinal lumen.

Even with this extension, however, it is not yet possible to explain many phenomena of absorption on a purely physical basis. Not only do the regulatory powers of the cell and its changing structure influence the course of diffusion processes but it seems probable that certain substances in their passage enter into chemical combination with constituents of the protoplasm thus making possible different types of selective transportation. Furthermore, white blood cells actually migrate back and forth between the lymph and the lumen of the intestine. There is evidence that certain of these may actually engulf particles of iron compounds and fat droplets. One of their functions may thus be to assist by phagocytosis in the absorption of difficultly soluble substances. Their number is hardly adequate to permit their playing a large role in the absorption of food-stuffs; however, their accumulation in the intestinal mucosa during digestion would indicate that their function is an important one.

The intestinal mucous membrane further possesses the power of excreting certain substances into the gut. Sucrose injected into the blood stream appears in part in the duodenum, and calcium salts are eliminated by the mucosa of the large intestine. The glands of the mucosa secrete a digestive fluid, the intestinal juice, and the cells themselves contain enzymes such as proteinases and peptidases, carbohydrases, and phosphatases which help to prevent the passage of incompletely decomposed proteins, carbohydrates, and organic phosphates into the blood.

Because of the many factors involved, the study of intestinal absorption offers certain difficulties. Investigation of the processes concerned helps, however, to throw light on permeability and other fundamental properties of protoplasm. It is further of the greatest practical importance to understand the factors governing the absorption of the many essential food-stuffs, and to determine the conditions under which there is a loss of the great protective power of the intestinal mucosa to detoxicate or prevent the absorption of toxic substances, which may be ingested or produced during digestion or putrefaction.

Mineral oil has been shown to interfere with the absorption of fat-soluble vitamins and various digestion products. Certain adsorbing agents used therapeutically also interfere, and all cathartics interfere because of the reduced time the products of digestion remain in the intestine.

**Absorption of Carbohydrates.** Carbohydrates are absorbed almost entirely as the simple monosaccharides, glucose, fructose, galactose, mannose, and the pentoses, each having a characteristic absorption rate. Cori showed that galactose was absorbed most rapidly. Next came glucose and fructose. L-Arabinose had the slowest absorption rate, less than one-tenth that of galactose and glucose. There is considerable evidence favoring the view that a hexokinase-catalyzed phosphorylation takes place in the intestinal absorption of glucose, followed by a dephosphorylation of the sugar by phosphatases in the intestine before it enters the circulation. Of the disaccharides, lactose is least readily hydrolyzed in the intestine and some of it occasionally reaches the blood as such. In these cases it is eliminated unchanged in the urine. Sucrose entering the blood is also excreted as such. When strong sugar solutions enter the bowel they are diluted by the intestinal secretion until the concentration is reduced to a point favorable for absorption; i.e., when the osmotic concentration equals that of the blood plasma. Lactose, because of its slow digestion and absorption, reaches a much lower portion of the bowel than other sugars and is thus more effective in promoting the growth of acidophilic rather than putrefactive bacteria.

The simple sugars entering the blood are quite rapidly removed therefrom by the liver and other tissues for oxidative and storage purposes. After the ingestion of 100 g. of glucose a maximum blood-sugar value of about 0.15 per cent is reached in less than an hour, the normal figure of about 0.1 per cent being restored by the end of two hours. This rapid absorption of glucose and its subsequent oxidation in the tissues to yield energy are of importance to persons engaged in prolonged athletic competition or in other fatiguing activities.

If the intestinal mucous membrane is destroyed, or poisoned by such a substance as sodium iodoacetate, it acts like an ordinary permeable membrane and sugars pass through it according to ordinary laws of diffusion. Thus the pentoses pass through more rapidly than the hexoses. With the normal living membrane, however, the hexoses show more rapid absorption. Apparently the hexoses are combined with phosphate in passing through the cells of the mucous membrane. The formation of this compound greatly speeds up the absorption process and makes possible absorption even from a sugar solution of lower concentration than the blood. The intervention of chemical mechanisms of the living cell also makes possible a certain selectivity in absorption, and an adaptation of the mucous membrane in the direction of self-protection of the body against rapid absorption of toxic substances.

**Absorption of Protein.** Protein is absorbed for the most part in the form of individual amino acids. The amino acid content of both portal and systemic blood rises after a meal. The amino acids of the diet entering the body are carried by the blood to all the tissues of the body, where they rapidly become incorporated into the metabolic processes of the cells and become indistinguishable from the amino acids already present unless they have been labeled in some way, as with isotopic nitrogen. Thus the dietary amino acids are not to be regarded as somewhat of a surplus, as they were at one time, to be drawn upon or oxidized as the need arose, but rather as a daily contribution to the general processes of nitrogen metabolism in the body (see Chapter 33).

Whereas proteins are absorbed mainly as amino acids, it is nevertheless true that certain molecules larger than the amino acid molecules, e.g., peptides or polypeptides, may at times be absorbed. *Streptogenin*, a peptidelike substance, is definitely absorbed.<sup>1</sup> With the aid of immunological methods it has also been established that certain unsplit proteins may be absorbed unchanged.

A variable and sometimes significant proportion of the dietary amino acids escape absorption and are metabolized by the bacteria of the intestinal tract. The products of this action may be absorbed and appear in the blood or urine. The relatively high ammonia content of portal blood is attributed to these processes, as is the indican content of the urine. The significance of such intestinal putrefaction is discussed in Chapter 20.

Incompletely decomposed protein may sometimes be absorbed, as is indicated by the production in certain individuals of anaphylactic reactions (cutaneous eruptions, asthma, etc.) following the ingestion of particular types of protein. Such reactions are not produced by completely hydrolyzed proteins.

**Absorption of Fat.** The exact mechanism by which fat is absorbed is the subject of considerable controversy. Two theories have been proposed, namely, the *lipolytic* and the *partition theory*, and each of these possesses certain merits. According to the lipolytic theory as defined by Bloor as well as by Verzář, a complete hydrolysis of the ingested fat occurs in the gastrointestinal tract as a preliminary to absorption. Glycerol formed as a result of such hydrolysis is readily soluble in water;

---

<sup>1</sup> Woolley: *Federation Proc.*, 6, 424 (1947).

there is considerable experimental evidence that this compound can be readily and completely absorbed. On the other hand, the fatty acids resulting from hydrolysis of the neutral fats are insoluble in water, although their soaps dissolve quite readily. However, the pH of the small intestine is such as to preclude the presence of appreciable amounts of soap. Since it is known that most fats are almost completely digested, some mechanism is required to transport the water-insoluble fatty acids through the gut wall if soaps are excluded. The mechanism seems to involve the presence of bile concomitant with the fat. Under such conditions an emulsion is formed which is reflected in the milky appearance (chyle) of the lymph in the mesenteric vessels during the absorption of fat. This condition does not obtain in the absence of bile. Bile is believed to facilitate digestion both by activating pancreatic lipase and also by rendering the fatty acids soluble in the aqueous medium. The latter change is mediated by the bile salts, which lower the surface tension. It has been postulated that the bile salts combine with the fatty acids to form compounds known as *choleic acids*. Wieland and others have demonstrated that such compounds, produced in the test tube, have definite melting points, and that there are fixed ratios of fatty acids to bile acids (usually 1:8 in the case of  $C_{16}$ - $C_{18}$  acids). The importance of this mechanism remains questionable, however, since the only naturally occurring bile acid which is active is deoxycholic acid, and this is a minor component in most biles. Moreover, only the unconjugated form is active; but the conjugated acids (glycodeoxycholic and taurodeoxycholic acids) represent the forms occurring in the bile. The fact that such coordination compounds as choleic acids exist is however an intriguing one, and these compounds may be related to fat absorption.

According to the partition theory, as proposed by Frazer, fats are only partially hydrolyzed in the gut, with the resultant formation of some fatty acids, and also mono- and diglycerides. The bulk of the fat is in the form of triglycerides. These lower glycerides and fatty acids, together with bile salts, form a stable emulsion which consists largely of triglyceride fats. This particulate matter, when the droplets are of a size of  $0.5\mu$  or less, is directly absorbable through the fine canals in the outer border of the intestinal cells. The results of Mattson *et al.* (see Chapter 33) tend to support this hypothesis. They showed that the intestinal contents of rats, removed three hours after the animals had been fed a mixture of partially hydrogenated cottonseed and soybean oils, contained principally unhydrolyzed triglycerides, diglycerides, and monoglycerides, with only 15 per cent of free fatty acids. Frazer is of the opinion that triglycerides of short-chain fatty acids, whose acids are water-soluble, may be completely hydrolyzed in the intestine.

There are ample experimental data which demonstrate that, irrespective of the fatty material fed, neutral fat appears in the intestinal lymph. According to the Verzár school, the products of fat digestion are recombined in the intestinal mucosa, possibly through the intermediation of phospholipide. Frazer also suggests that considerable modification and resynthesis of triglycerides may occur in the intestinal cells. The bile acids set free are returned to the lumen of the gut to assist in the absorption of additional fat. Although new phospholipides may be formed in

the intestinal cells, as demonstrated by the incorporation of the unnatural fatty acid *elaidic acid* in the intestinal phospholipides after the feeding of *tri-elaidin* (Sinclair), considerable quantitative data are now available which indicate that the phospholipides are not obligatory intermediates in fat synthesis.

By means of tests (rats) in which decanoic and palmitic acids labeled with  $C^{14}$  in the carboxyl position were fed, it was learned that short-chain fatty acids are transported mainly by the portal pathway, and long-chain saturated fatty acids via lymph.<sup>2</sup>

After resynthesis, the greater part of the fat first enters the lacteals of the intestinal villi and then the lymphatics, forming an emulsion (the chyle) which is carried via the thoracic duct to the jugular vein. An increase in the fat content of the blood and lymph following a meal ("fat tide") is readily demonstrated, the fat appearing in the form of minute globules called chylomicrons. The fat of the diet is therefore unique among the other components of the diet in that in large part it bypasses the liver. The significance of this anatomical arrangement is not clear, but it may possibly be related to the recognized ability of liver tissue to oxidize fatty acids rapidly to the stage of acetoacetic acid and  $\beta$ -hydroxybutyric acid.

**Absorption of Sterols.** Cholesterol, the most important of the sterols, like the fatty acids forms compounds with the bile acids which facilitate its absorption (see Chapter 18). Unabsorbed cholesterol is reduced to coprosterol. It is uncertain whether this change to coprosterol is brought about solely through bacterial action. The plant sterol phytosterol is not absorbed and hence cannot become a source of cholesterol in the animal body. Ergosterol is said to be absorbed but slightly if at all; but the irradiated form (calciferol) is more readily absorbed. Apparently the absorption of sterols is very specific, so that even isomerism may alter absorbability, and saturation of unsaturated bonds may change a sterol from a readily absorbable substance to one completely unabsorbable. Of the many sterols found in plant or animal foods, the only one which is absorbed in the human intestine, aside from the D vitamins, is cholesterol. Certain forms of vitamin D are absorbed to different degrees in different species (see Chapter 35).

**Absorption of Inorganic Salts.** The selective nature of absorption applies even to inorganic salts. Thus sulfates are much less readily absorbed than chlorides and tend to withdraw water from the blood. For this and other reasons the sulfates have a cathartic effect. The absorption of calcium and phosphorus is of especial interest because of its relation to the development of rickets and because this absorption can be so profoundly affected by minute amounts of antirachitic vitamin and hence by ultraviolet radiation. The acidity of the intestinal contents is also of importance for the absorption of the relatively insoluble salts of calcium. The most rapid rate of absorption of calcium after the administration of  $CaCl_2$  solution containing  $Ca^{45}$  has been found to occur within the first 2 to 4 hours. This absorption was principally from the proximal part of the small intestine.<sup>3</sup> Dietary iron appears to be absorbed in nutritionally

<sup>2</sup> Kiyasu, Bloom, and Chaikoff: *J. Biol. Chem.*, **199**, 415 (1952).

<sup>3</sup> Harrison and Harrison: *J. Biol. Chem.*, **188**, 83 (1951).

significant amounts only when it is in the ionized inorganic form, and clinical and experimental evidence indicates that ferrous iron is much more available for absorption than ferric iron. Calcium, magnesium, phosphorus, and iron are excreted to a considerable extent by the intestinal mucosa. Hence a study of their absorption at different levels of the intestinal tract is required for an understanding of the factors involved. The absorptive power of the colon for food substances is relatively low.

**Methods of Studying Absorption.** Much of our information on absorption has been obtained from the study of isolated intestinal loops which retain their nerve and blood supply. Solutions can be injected into such loops and the contents removed at any time for analysis. The relative rates of absorption of various substances can thus be determined under controlled conditions. Small animals such as the rat may be sacrificed after the ingestion of test substances, the intestinal tract removed, washed out, and the washings then analyzed to establish the extent of absorption.

Histological examination of the mucosa of animals killed after a meal has shown the presence of fat globules in the cells.

By establishing fistulas of the intestine, the course of absorption in different parts of the tract has been studied.

Analysis of the blood and lymph gives information of great importance relative to the nature of the products entering the blood stream. Urine analyses show the rapidity with which soluble inorganic salts are absorbed. Perfusion experiments on the intestine are little used because a normal mucous membrane is difficult to maintain. Studies on absorption from the stomach may be made with a stomach tube, and a similar procedure may give some information as to absorption from the colon. Fecal analyses show the completeness of digestion and absorption of various substances present in the food.

Animals may also be fed a diet containing a definite amount of a non-absorbable substance such as iron oxide, or a labeled component such as elaidic acid or compounds containing the isotopes of hydrogen, phosphorus, nitrogen, iron, or carbon. By suitable analyses of the intestinal contents and the other parts of the animal body the rate and extent of absorption may be evaluated. The use of isotopes in particular appears to offer great promise in elucidating the mechanism of absorption. For a discussion of isotopes, see Chapter 32, p. 970.

## EXPERIMENTS ON ABSORPTION

**1. Experiment to Show the Action of Bile Salt Solutions on Fatty Acids and Cholesterol.** Prepare five test tubes as follows:

a. Five ml. of buffer solution pH 7 + 2 ml. of a 10 per cent solution of bile salts + 1 ml. of a 1 per cent solution of oleic acid in alcohol.

b. Five ml. of buffer solution pH 7 + 2 ml. of water + 1 ml. of 1 per cent oleic acid solution.

c. Five ml. of buffer solution pH 9 + 2 ml. of water + 1 ml. of 1 per cent oleic acid solution.

d. Five ml. of water + 2 ml. of 10 per cent bile salt solution + 1 ml. of a 0.05 per cent solution of cholesterol.

e. Five ml. of water + 2 ml. of water + 1 ml. of cholesterol solution.

Place all tubes in a water bath at 40° C. for a few minutes and observe the tubes for turbidity.

Fatty acids form a clear soap solution only at pH 9 or higher. With bile salts a clear and diffusible solution is formed even below pH 7. Bile salts also have a similar action on cholesterol. This is important also in connection with the excretion of cholesterol in the bile.

**2. Determination of Rapidity of Absorption of Sugars from the Entire Gastrointestinal Tract (Method of Cori): Principle.** Animals are given sugar solutions by a stomach tube. After a suitable time has elapsed the animals are killed, the entire gastrointestinal tract removed, and the total sugar remaining unabsorbed determined.

**Procedure.** Rats two to three months old and weighing from 120 to 180 g. are weighed. They are then placed in small wire-screen cages with screen bottoms so that there is no access to feces. For 48 hours they are given water but no food. The rats are again weighed and are then fed the solutions to be tested, usually 1.25 to 2.5 ml. of 25 to 80 per cent sugar solutions. These are introduced by means of stomach tubes consisting of Nos. 4 to 5 urethral catheters softened by plunging for a moment into boiling water. A small mouthpiece is used and the catheter marked to indicate the depth to which it should be introduced. A syringe of the Record type with a needle to connect with the catheter is used to inject the fluid. If diarrhea is caused the experiment is discarded.

An animal is killed at each hourly interval. The entire gastrointestinal tract is removed, slit open, and washed thoroughly with water making up to a volume of nearly 500 ml. A small amount of dialyzed iron is added and then a little sodium sulfate to precipitate it, along with interfering substances. The sugar is determined by the Benedict method or some other method. Blood sugar may also be determined by the Hagedorn-Jensen method or other micro method. Sugar may also be determined in the urine. (In another experiment it may be shown by analysis of the gastric contents that a dilution of the sugar solution takes place in the stomach.) The amount of sugar absorbed per 100 g. of body weight of the animals is calculated. An absorption curve may also be plotted from the results obtained with similar animals at 1, 2, 3, 4, etc., hours. Cori found that the rate of absorption of hexoses is independent of the concentration, and the rates of absorption of some monosaccharides are in the following order: galactose > glucose > fructose > mannose > xylose > arabinose. No glucose appeared in the urine but about 50 per cent of the galactose was excreted by this channel.

If a soluble ferric salt such as ferric ammonium citrate is added to the sugar solutions it is possible to determine in what parts of the tract digestion and absorption of carbohydrates, etc., more particularly occur (see the experiment below).

The tolerance of animals for sugars injected intravenously may also be determined and an idea obtained as to the rapidity with which sugars are absorbed when injected intravenously as compared with absorption from the intestine. Cori found the tolerance for glucose given intravenously to be from 2.2 to 2.5 g. per kg. of body weight per hour.

**3. Influence of Carbohydrates on the Utilization of Calcium and Phosphorus (Method of Bergeim<sup>4</sup>): Principle.** To a standard diet is added a definite

<sup>4</sup> Bergeim: *J. Biol. Chem.*, 70, 29 (1926); Gallup: *J. Biol. Chem.*, 76, 43 (1928); Heller, Breedlove, and Likely: *J. Biol. Chem.*, 79, 275 (1928). For use of silica see Greenwald and Gross: *J. Biol. Chem.*, 66, 185 (1925); 82, 505 (1929); Gallup: *J. Biol. Chem.*, 81, 321 (1929).

For use of the iron method in the study of digestion and absorption in different parts of

proportion of iron oxide and of the carbohydrate whose effect it is desired to study. The ratios of calcium and phosphorus to iron are determined for foods and feces and the percentage absorption calculated. The accurate separation of feces of the experimental period is not necessary.

**Procedure.** Feed two or more albino rats (about 60 g. in weight) on a phosphorus-low and calcium-high diet (whole yellow corn 76, wheat gluten 20, calcium carbonate 3, sodium chloride 1, and c.p. ferric oxide 0.2) for about three weeks. Put in separate cages with screen bottoms. Collect feces for a five-day period. Then modify the diet of the animals by substituting glucose for 30 parts of corn in one case, and an equal amount of lactose in the other. After a two-day interval, collect the feces for a period of four days. Then exchange diets so that the first animal gets lactose and the second glucose. After a two-day interval collect feces again over a four-day period. All feces need not be collected. Those contaminated with urine are discarded.

About 0.5 g. (not weighed) of feces from each collection is ashed, preferably in a 35-ml. silica crucible at a moderate temperature. Add a few drops of nitric acid to the residue and heat again to destroy the last carbon. Add 10 ml. of 15 per cent hydrochloric acid and heat until the ash is dissolved. Wash into a flask with water to make about 35 ml. Ash 2 g. of food and dissolve the ash in the same way. Determine iron, calcium, and phosphorus in the ash solutions by standard methods (see Chapters 23 and 31) and record the number of mg. of each in 1 ml. of ash solution.

**CALCULATION.** Calculate the ratios Ca/Fe and P/Fe for food and feces, and calculate percentage absorption or utilization of Ca and P. For example, if the ratio Ca/Fe for food is 10:1 and in feces 4:1, unabsorbed Ca is 4/10 or 40 per cent, and utilization is  $100 - 40 = 60$  per cent.

Lactose promotes calcium absorption by creating an acid medium (lactic acid) in the intestines. Glucose has little effect. Vitamin D markedly improves absorption of Ca and P.

## Putrefaction, Detoxication, and Conjugation

The food residue and the digestive and other secretions as they pass into the lower ileum and colon are acted upon by the bacterial flora which become permanently established in man during the first few days of life. The extent of bacterial activity is indicated by the fact that nearly one-third of the solid matter of normal feces is made up of bacteria.

The metabolic products of the intestinal bacteria are for the most part harmless, and some are actually useful; but a few, especially those arising from proteins and amino acids, are toxic in varying degrees. In the past it was believed that an excess production of these products, such as might occur in constipation, caused a condition of autointoxication characterized by malaise, headache, and irritability. Probably mechanical factors as well as emotional and psychic influences often account for some of these disagreeable effects attributed to constipation.

When amino acids are acted upon by bacterial enzymes, they undergo decarboxylation, deamination, and other reactions, with the result that abnormal products are formed. Some of these are toxic and are handled in the body by chemical mechanisms that are generally regarded as detoxifying. The variety of products that may result from an amino acid is illustrated by tyrosine.

**Action of Products of Putrefaction.** Of the various types of compounds formed by bacteria acting on amino acids, the amines are physiologically the most active. Tyramine, which is formed from tyrosine, is a strong vasoconstrictor and like epinephrine, to which it is closely related structurally, it elevates blood pressure. Histamine, on the contrary, causes capillary dilatation. Although this compound may be formed by bacterial action, it is also normally produced by the body to serve as a stimulus for the secretion of hydrochloric acid in the stomach. In anaphylactic shock large amounts of histamine are released into the circulation. Since tryptamine is a product of putrefaction, it is interesting to recall that when platelets disintegrate during the clotting reaction, 5-hydroxytryptamine is produced.<sup>1</sup> This compound is a strong vasoconstrictor and probably plays an important role in hemostasis. Of the aliphatic amines, two are well known: pentamethylenediamine (cadaverine) and tetramethylenediamine (putrescine), which are derived from lysine and arginine respectively. Since they were originally isolated from putrefying flesh, they were classed as ptomaines. In spite of their offensive names, they are relatively harmless. The condition known as ptomaine poisoning is due to bacterial toxins and not to these amines.

Of the putrefactive products other than amines, indole and skatole, which are derived from tryptophan, have received much attention. Both possess a disagreeable odor and are mainly responsible for the characteristic odor of feces. Only a small fraction of the indole and skatole formed in the intestines is absorbed, as indicated by the finding that the daily excretion of indican (indoxyl potassium sulfate) rarely exceeds 10 to 20 mg. It is improbable that such small amounts have any deleterious effects. Phenol, *p*-cresol, and allied compounds formed from aromatic amino acids are toxic, but the quantities formed and absorbed are rarely large enough to be harmful provided the liver and kidneys function normally. Total phenol excretion by normal men averages about 0.2 g. per day.

Some of the bacterial products formed in the intestines are distinctly useful to the body. It is likely that part of the vitamin K required by the organism comes from the action of *E. coli* and other bacteria. It is known that various other vitamins such as biotin and thiamine are synthesized by bacteria, and that these can be utilized by the body. The bacterial flora may therefore be regarded as an auxiliary factor in nutrition. The benefits thus accruing are likely to outweigh the harm that may come from the toxic putrefactive products.

## DETOXICATION

Though it is well known that the body can and does develop means of defense against microorganisms and their toxins, which usually are proteins, there is no convincing proof that it has evolved mechanisms specifically intended to detoxify either the products resulting from putrefaction in the intestines or the myriads of compounds and drugs that are ingested and absorbed.

---

<sup>1</sup> Rapport, Green, and Page: *J. Biol. Chem.*, **180**, 961 (1949).

In general, all products of exogenous origin that enter the body may be divided into three major classes: (1) Substances which are normally utilized for energy, structure, or function. All may be broadly considered as food. (2) Substances which, in the doses ingested, alter physiological function. If the change in function is beneficial, the substance producing it is considered to be a drug; whereas if the alteration is harmful, the substance is considered to be a poison. (3) Substances which pass through the body unaltered and cause little or no change in function. Water is the most important example, although in a strict sense it may be regarded as a food.

In categories as broad as these, many instances of overlapping as well as difficulties of interpretation arise. Ethyl alcohol may be regarded as a food, a drug, or a poison. Similarly, nicotinic acid, being a vitamin, is a food; but it may also act as a drug and in large doses as a poison.

Although the protection against noxious substances is probably largely accidental rather than by design, detoxication nevertheless plays an important physiological role. It begins in the intestines. Thus, the enzyme histaminase, found in the alimentary tract, is probably responsible for the destruction of relatively large amounts of histamine. The intestinal wall is coordinated in the line of defense against poisons, since it acts as a barrier to various harmful substances. Many toxic substances that pass the intestinal walls are removed by the liver. It is not surprising therefore that this organ, which has as one of its functions that of a chemical watchdog, possesses many of the mechanisms which are usually designated as detoxication reactions. The principal reactions, namely, oxidation, reduction, hydrolysis, and conjugation, which the body normally employs for the destruction, detoxication, and elimination of a foreign compound are not essentially different from those employed on normal metabolites. Many foreign substances are only partially metabolized, thereby leaving a chemical clinker or residuum which often serves as a valuable source of information concerning metabolic pathways.

**Oxidation, Reduction, and Hydrolysis.** The first attempt of the body to protect itself against a toxic compound is to destroy it by oxidation. Many substances such as ethyl alcohol are completely burned to carbon dioxide and water. Sometimes the intermediary oxidation products are more toxic than the original compound, as illustrated by methyl alcohol, which yields formaldehyde and formic acid.

The oxidation of aromatic compounds is of great physiological importance. Benzene itself as well as many simple aromatic compounds such as benzoic acid and phenol are fairly resistant to oxidation. Certain side chains, particularly the groups  $\text{CH}_2\text{CH}(\text{NH}_2)\text{COOH}$ , which occurs in phenylalanine, and  $\text{CH}_2\text{CO}\cdot\text{COOH}$  render the aromatic nucleus completely oxidizable. This suggests that oxidative deamination is the initial step in the metabolism of amino acids.

Of particular interest is the oxidation of phenyl-substituted fatty acids. Oxidation takes place on the  $\beta$ -carbon atom, and the side chain is progressively reduced by two carbon atoms, so that ultimately the aromatic acids

having a side chain with an odd number of carbon atoms yield benzoic acid, and those with an even number yield phenylacetic acid.

From these observations Knoop formulated the hypothesis that normal fatty acids are likewise catabolized by  $\beta$ -oxidation (see Chapter 33).

The finding<sup>2</sup> that the depancreatized dog oxidizes phenylbutyric acid to phenylacetic as readily as a normal dog is interesting because it was the first evidence suggesting that the oxidation of butyric acid was not impaired in diabetes.

Reduction and hydrolysis are encountered infrequently in the metabolism of foreign compounds. One example of reduction is the conversion of chloral hydrate to trichloroethyl alcohol, which is then combined with glucuronic acid. Glucosides such as the digitalis compounds probably undergo hydrolysis with the liberation of a sugar and an aglycone as a step in their metabolism and elimination from the body.

The conversion of cyanide to thiocyanate may be regarded as an important detoxication mechanism. This is indicated by the wide distribution in various tissues of the enzyme rhodanese, which is responsible for changing cyanides to thiocyanate, and also by the relatively high concentration of thiocyanates in the blood (over 1 mg. per 100 ml.). The reaction may be expressed as:

The source of the sulfur is not known. It can be supplied by thiosulfate *in vitro*, but it remains uncertain whether this compound is utilized physiologically.

**Conjugation.** The isolation by Keller in 1842 of hippuric acid after the ingestion of benzoic acid led to the recognition of a new type of biochemical reaction, namely, the conjugation of a foreign organic compound with a normal metabolic product such as glycine. Other compounds or radicals employed by the organism for conjugation are glucuronic acid, sulfuric acid, cysteine, glutamine, ornithine, acetic acid, and the methyl group.

**Antimetabolites.** Though it is generally assumed that conjugated products are the resultants of detoxication, it is more likely that they are merely the end products of normal metabolic processes applied to foreign compounds. When any ingested compound is excreted in a conjugated form, it may be regarded as an antimetabolite (see Chapter 36). One may postulate that such a compound has enough structural similarity to a normal metabolic product to engage the enzyme designed for the latter.

<sup>2</sup> Quick and Sweet: *J. Biol. Chem.*, **80**, 527 (1928).

As a result the normal activity of the enzyme is decreased, and it produces an abnormal product which cannot be further metabolized and is therefore excreted.

Valuable information has been gained from the study of those conjugated compounds which were the first historically to serve as metabolic tracers. Knoop, as already stated, postulated the theory of  $\beta$ -oxidation from his observations of the end products of phenylaliphatic acids. Glycine, glutamine, ornithine, sulfuric acid, and glucuronic acid were discovered as constituents of conjugated products long before it was recognized that these compounds participated actively in many normal physiological processes. Methylation of pyridine and nicotinic acid was noted decades before biochemists had any appreciation of the essential role of this reaction in metabolism.

The type of conjugation is determined by the active chemical groups in the molecule, but important modifications are brought about by secondary groups not directly concerned in the conjugation. Marked species differences in conjugation occur.

**The Carboxyl Group.** The introduction of a carboxyl group into the benzene ring is one of the most effective means of reducing toxicity. Thus the addition of the COOH group to phenol produces salicylic acid, a non-toxic compound. Toluene, which the body oxidizes to benzoic acid, is less toxic than benzene, which yields on oxidation phenol, polyphenols, and muconic acid. Benzoic acid is the type compound in which a carboxyl group is attached to the benzene ring. In man nearly all of the compound is combined with glycine to form hippuric acid. There is good evidence that the synthesis occurs primarily in the liver. The quantitative estimation of the excretion of hippuric acid following the administration of benzoic acid is therefore a satisfactory test of liver function. With this method, the body's capacity to synthesize glycine and to conjugate it with benzoic acid are measured. The organism can utilize waste nitrogen for this synthesis, but the exact reactions involved are not known.

Rather than postulate that the body possesses a mechanism specifically designed to synthesize hippuric acid, it is more reasonable to suppose that benzoic acid has enough structural resemblance to a metabolite normally conjugated with glycine by a particular enzyme system to be acted upon by the same enzyme. As a result, benzoic acid is conjugated with glycine to form hippuric acid, which is excreted because it cannot be further

metabolized. During the period that benzoic acid is being conjugated, the enzyme is inhibited from carrying out its normal function. Evidence

of such a metabolic depression is the observation that the excretion of uric acid is strikingly decreased after the ingestion of benzoic acid.

Substitutions in the benzene ring of benzoic acid alter the pattern of conjugation. Any group in ortho position strikingly slows or inhibits the conjugation with glycine. This is well illustrated by the important drug, salicylic acid. Irrespective of the size of the dose, little of the compound is combined with glycine and excreted as salicyluric acid. Interestingly, when the hydroxy group is in para position, man excretes about one-half of the ingested compound unconjugated, and the other half combines with glycine to form *p*-hydroxyhippuric acid. *p*-Methoxybenzoic acid, in marked contrast, is half conjugated with glucuronic acid and the remainder with glycine.

Phenylacetic acid differs sufficiently in structure from benzoic acid to require a different enzyme for its conjugation. This is demonstrated by the fact that when both kidneys are removed from a dog, the animal loses the power to synthesize hippuric acid, but retains the ability to form phenylaceturic acid. It is of considerable interest that phenylacetic acid is the only compound known to be conjugated with glutamine. This synthesis has been observed only in man and in the chimpanzee. In the avian organism both benzoic and phenylacetic acid are conjugated with ornithine.

The dog, in contrast to man and the rabbit, conjugates nearly 75 per cent of the ingested benzoic acid with glucuronic acid. The source of this compound remains unknown. Free glucuronic acid is poorly metabolized, and since it is not found in the unconjugated form, it seems unlikely that a

direct union of glucuronic acid and benzoic acid occurs. The observation that the completely diabetic organism retains the ability to form conjugated glucuronides, apparently from the fraction which would be excreted as glucose, shows that glucogenic amino acids can serve as a source of glucuronic acid. Whether the foreign compound is combined with glucose with subsequent oxidation to glucuronic acid or whether the glucuronic acid is synthesized from three carbon compounds remains unsolved. The wide distribution of the enzyme  $\beta$ -glucuronidase in the body and the observation that various sex hormones are combined and excreted with glucuronic acid clearly indicate that this compound occupies a prominent position in metabolism.

**The Hydroxyl Radical.** A compound such as phenol is conjugated with both glucuronic acid and sulfuric acid. The latter type of compound is called an ethereal sulfate. Indican, which is the common name for indoxyl-sulfuric acid, is historically important since it has been used as a measure of intestinal putrefaction. The organism apparently can combine sulfuric acid directly with a phenol. Chloral hydrate ( $\text{CCl}_3\text{CH}(\text{OH})_2$ ) a commonly employed sedative, is reduced in the body to trichloroethyl alcohol, which is conjugated with glucuronic acid.

**The Aromatic Amino Group.** Though aniline is extremely toxic, its acetyl derivative, acetanilide, is a relatively nontoxic drug. It would appear logical therefore to expect acetylation to be an important detoxication reaction. Actually there is little evidence that this is true. Sulfanilamide and its various derivatives are acetylated in the body. Their therapeutic effectiveness is thereby lost, but their toxicity does not appear to be significantly lowered. Interestingly, the vitamin *p*-aminobenzoic acid is acetylated and excreted. Although acetylcholine is an important physiological compound, acetylation of other hydroxy compounds, particularly nonmetabolites, has apparently not been observed.

**The Pyridine Ring.** Pyridine, quinoline, and many of their derivatives are methylated in the body. The transfer of a methyl group to nuclear nitrogen is apparently a common reaction. Nicotinic acid is methylated to form trigonelline. Since its antipellagra properties are thereby lost, the purpose of such a reaction is not clear.

**The Benzene Ring.** When benzene or polycyclic hydrocarbons such as naphthalene and anthracene are ingested, their corresponding mercapturic acids can be isolated from the urine. In this conjugation, the sulfur of cysteine becomes directly combined with a nuclear carbon atom, and the amino group becomes acetylated. *p*-Bromophenylmercapturic acid formed from bromobenzene is the best known since it can be isolated fairly easily. Rather than regard this conjugation as a detoxication process, it seems more reasonable to suppose that it serves as a means for introducing hydroxy groups into the benzene ring, which is a step in the metabolism of the aromatic nucleus. This assumes that the body possesses an enzyme which splits the acetylated cysteine from the benzene ring by hydrolysis.

The conjugation reactions should be regarded as important metabolic processes rather than biochemical oddities. The ease with which the body furnishes glycine, glucuronic acid, acetic acid, cysteine, and other conjugating components serves as evidence of their wide and important utilization in metabolism. Interestingly, the avian organism lacks the ability to form hippuric acid, but conjugates aromatic acids with ornithine. This suggests the close relationship of some of the conjugating reactions with the Krebs-Henseleit urea cycle.

## EXPERIMENTS

### INDOLE AND SKATOLE

**1. Herter's  $\beta$ -Naphthoquinone Reaction.** To 10 ml. of unknown solution add 2 drops of 2 per cent solution of  $\beta$ -naphthoquinone sodium monosulfonate and 2 ml. of 10 per cent NaOH. Let stand 15 minutes. Shake with 2 ml. of chloroform. A pinkish-red color in the chloroform indicates indole. This is a very delicate test.

**2. Ehrlich's *p*-Dimethylaminobenzaldehyde Reaction.** To 10 ml. of unknown solution add 1 ml. of 5 per cent alcoholic solution of *p*-dimethylaminobenzaldehyde and 1 ml. of concentrated HCl. Indole gives a red color and skatole a blue color.

### PHENOLS, HYDROXY AROMATIC ACIDS, AND IMIDAZOLES

**Conjugation with Glucuronic Acid and Glycine: Principle.** The fate of anisic acid (*p*-methoxybenzoic acid) in the body illustrates the influence exerted by a relatively inert chemical group such as the methoxy radical when introduced into the benzene ring of benzoic acid. In the human organism benzoic acid is conjugated almost entirely with glycine to form hippuric acid, whereas only about 50 per cent of *p*-methoxybenzoic acid is combined with glycine; the remainder is conjugated with glucuronic acid. When glycine or gelatin is given with the anisic acid, the amount of *p*-methoxyhippuric acid excreted is greatly increased without, however, depressing the conjugation with glucuronic acid.

**Procedure.** 3 g. of anisic acid is neutralized exactly with 10 per cent sodium hydroxide, using phenolphthalein as the indicator. The solution is diluted to 30 ml. and ingested. 200 ml. of water are drunk. The subject voids immediately after taking the drug, and then collects complete hourly specimens for three hours. Each specimen is measured and its reducing action tested by mixing five drops with 5 ml. of Benedict's qualitative sugar reagent in a test tube and heating. The glucuronic acid can also readily be determined quantitatively by using Benedict's quantitative sugar method. 10 ml. of Benedict's quantitative reagent is transferred to a small Erlenmeyer flask or porcelain evaporation dish and 4 g. of anhydrous sodium carbonate added. The mixture is heated to boiling and the undiluted urine added from a 5-ml. Mohr pipet until the blue color completely disappears. This is a preliminary determination. For more exact results the urine is so diluted that about 10 ml. of the diluted urine is required to reduce 10 ml. of the reagent. The same quantity of Benedict's reagent and sodium carbonate as before is used. The diluted urine is delivered with a buret into the reagent, which is kept boiling. The glucuronic acid equivalent is approximately the same as that of glucose. The glucuronic acid may also be determined photometrically

by the naphthoresorcinol test.<sup>3</sup> The remainder of the sample is acidified with 1 ml. of concentrated hydrochloric acid and stirred to precipitate *p*-methoxyhippuric acid. Inoculation with a small crystal of the compound will hasten precipitation. The crystalline product is filtered by suction, washed with a small amount of cold water, and dried. From the weight of the product plus the amount calculated that remained in solution (100 ml. of urine dissolve 0.24 g. of *p*-methoxyhippuric acid), the quantity of anisic acid which is conjugated with glycine can be calculated.

### QUANTITATIVE BROMINATION

**Method of Day and Taggard:**<sup>4</sup> **Principle.** Phenol, aniline, and many of their derivatives such as hydroxy- and aminoaromatic acids are readily brominated. A quantitative replacement of one or more nuclear hydrogens by bromine occurs. From the amount of bromine consumed, the quantity of aromatic compound is calculated.

**Procedure.** 0.2 g. of *p*-methoxyhippuric acid obtained in the preceding experiment and purified by recrystallization from hot water is neutralized with sodium hydroxide and diluted to 75 ml. The solution is quantitatively transferred to a 500-ml. glass-stoppered bottle, and 25 ml. of 0.2 N bromate solution (75 g. of KBr and 5.6 g. of KBrO<sub>3</sub> per liter) is added. The solution is acidified with 5 ml. of concentrated hydrochloric acid and shaken for one minute. After 30 minutes the reaction bottle is cooled in ice or under the tap. The stopper is dislodged sufficiently to permit adding 5 ml. of 40 per cent KI solution. Care must be taken to prevent bromine vapor from escaping. The liberated iodine is titrated with 0.1 N sodium thiosulfate, using starch solution as indicator. The amount of bromine consumed is calculated from the difference between the number of ml. of thiosulfate required in the titration of the sample and the titration of the blank using 25 ml. of 0.2 N bromate solution.

**CALCULATION.** The bromine is supplied by the reaction:

One molecule of *p*-methoxyhippuric acid reacts with one molecule of bromine:

Each ml. of 0.1 N thiosulfate is equivalent to 0.01045 g. of *p*-methoxyhippuric acid.

For the bromine equivalent of other amino and phenolic compounds the original articles of Day and Taggard and of Quick should be consulted.

## Feces

**General.** The feces include the residue remaining in the intestine after the digestion and absorption of food together with products of intestinal secretion, epithelial debris, and bacterial growth and decomposition.

They are composed of the following substances:

1. Food residues, i.e., those portions of the food which either escape or are incapable of digestion and absorption.
2. The remains of the intestinal and digestive secretions not destroyed or reabsorbed.
3. Substances excreted into the intestinal tract, notably phosphates and other salts of calcium, iron, and other metals.
4. The bacterial flora of the intestinal tract and their metabolic end products.
5. Cellular elements to which may be added, under pathological conditions, blood, pus, mucus, serum, and parasites.
6. Abnormally, enteroliths, gallstones, and pancreatic calculi.

The amount of the fecal discharge varies with the individual and the diet. Upon an ordinary mixed diet various authorities claim that the daily excretion by an adult male will aggregate 110–170 g. with a solid content ranging between 25 and 45 g.; the fecal discharge of such an individual upon a vegetable diet will be much greater and may even be as great as 350 g. and possess a solid content of 75 g. In the authors' experience the average daily output of moist feces, calculated on the basis of data secured from the examination of over 1,000 stools, was about 100 g. The variation in the normal daily output is so great that this factor is of very little value for diagnostic purposes, except where the composition of

### INFLUENCE OF DIET ON FECAL DRY MATTER

|      | <i>Diet</i>           | <i>Dry Matter<br/>(Per Cent)</i> |
|------|-----------------------|----------------------------------|
| Milk | { Nursing infant..... | 15.0                             |

|      | Mixed diet.....       | 26.0                             |

the diet is accurately known. Lesions of the digestive tract, defective absorptive function, or increased peristalsis, as well as an admixture of mucus, pus, blood, and pathological products of the intestinal wall, may

cause the total amount of excrement to be markedly increased. An idea of the variation of the percentage of dry matter in the feces, evacuated after the ingestion of different diets, may be gathered from a consideration of the preceding table.

**Fecal Pigments.** The principal pigment of the feces is stercobilin which is chemically identical with the urobilin of urine, and like it is formed by oxidation of a chromogen stercobilinogen (or urobilinogen). This explains the darkening of stools upon exposure to air. The primary precursor of these compounds is bilirubin, which is reduced by intestinal bacteria to mesobilirubinogen; in the presence of a factor from bile this intermediate is transformed to urobilinogen or stercobilinogen, according to the relations shown on p. 413. A rapid decline to negligible amounts of urobilinogen in the feces, bile, and urine has been shown to follow the administration of aureomycin in therapeutic doses. Neither bilirubin nor biliverdin occurs normally in the fecal discharge of adults, although the former may be detected in the excrement of nursing infants. If these pigments are found in the feces of adults, they indicate an abnormally rapid transit through the large bowel, preventing their transformation into stercobilinogen. A simple method has been suggested<sup>1</sup> for the isolation of stercobilin and urobilin from the feces in crystalline form. The color of the fecal discharge is greatly influenced by the diet. A mixed diet, for instance, produces stools which vary in color from light to dark brown, an exclusive meat diet gives rise to a brownish-black stool, whereas the stool resulting from a milk diet is invariably light colored. Drugs and certain pigmented foods, such as cocoa, beets, the chlorophyllic vegetables, and various varieties of berries, each afford stools having a characteristic color. This is well illustrated by the occurrence of yellow stools following the administration of rhubarb, senna, or santonin, and of red stools following prontosil treatment. The green color of the calomel stool is generally believed to be due to biliverdin. The black stools following the administration of bismuth or iron drugs result from the formation of metallic sulfides or suboxides. In cases of biliary obstruction the absence of pigment and the presence of excess fat result in the formation of grayish-white acholic stools. Barium meals used in roentgenographic diagnosis impart a clay-white color to the feces.

**Odor.** Under normal conditions the odor of feces is due to skatole and indole, two substances formed in the course of putrefactive processes occurring within the intestine (see Chapter 20). Such compounds as methyl mercaptan, hydrogen sulfide, and similar substances resulting from bacterial putrefaction may also add to the disagreeable character of the odor. The intensity of the odor depends to a large degree upon the character of the diet, being very marked in stools from a meat diet, much less marked in stools from a vegetable diet, and frequently hardly detectable in stools from a milk diet. Thus the stool of the infant is ordinarily nearly odorless and tends to be rancid rather than putrefactive; it is believed that any decided odor may generally be readily traced to some pathological source.

<sup>1</sup> Watson, Lowry, Sborov, Hollinshead, Kohan, and Matte: *J. Biol. Chem.*, **200**, 697 (1953).

**Reaction.** Experiments in which the actual hydrogen-ion concentration of the feces was determined indicate that the normal reaction of the excreta is slightly alkaline (pH 7.0 to 7.5). Pronounced dietary changes, (e.g., low-protein diet, high-protein diet, fasting, water-drinking with meals) produce at most only minor changes in the reaction of the feces. The ingestion of large amounts of lactose may cause the production of an acid reaction.

**Consistency.** The form and consistency of the stool is dependent, in large measure, upon the nature of the diet. Under normal conditions the consistency may vary from a thin, pasty discharge to a firmly formed stool. Stools which are exceedingly thin and watery ordinarily have a pathological significance. In general the feces of the carnivorous animals are of a firmer consistency than those of the herbivora.

The continued ingestion of a diet which is very thoroughly digested and absorbed is frequently accompanied by the formation of dry, hard, fecal masses (*scybala*). Constipation generally results from the small bulk of the feces and its lack of moisture. At present the formation of *scybala* is considered pathological, as an expression of spastic constipation. To counteract this tendency toward constipation the ingestion of agar-agar, psyllium seed, or other vegetable gums is practiced. These are relatively indigestible and readily absorb water, thus forming a bulky fecal mass which is sufficiently soft to permit easy evacuation. Mineral oil, because of its lubricating and softening properties is much used as an aid in overcoming constipation. Though it is inert and practically nonabsorbable, excessive amounts of mineral oil may interfere with the absorption of fat-soluble vitamins.

**Separation.** It is frequently desirable for clinical or experimental purposes to make an examination of the fecal output which constitutes the residual mass from a certain definite diet. Under such conditions, it is customary to cause the person under observation to ingest at the beginning and end of the period in question some substance sufficiently different in color and consistency from the surrounding feces to render comparatively easy the differentiation of the feces of that period from the feces of the immediately preceding and succeeding periods. One of the most satisfactory methods of making this separation is by means of the ingestion of a gelatin capsule containing about 0.2 g. of powdered charcoal at the beginning and end of the period under observation. This procedure causes the appearance of two black zones of charcoal in the fecal mass. A capsule containing carmine (0.3 g.) may be used in a similar manner and forms two dark red zones. Chromic oxide ( $\text{Cr}_2\text{O}_3$ ) has also been suggested for this purpose.<sup>2</sup> Some similar method for the separation of feces is usually practiced in connection with accurate nutrition or metabolism experiments conducted for the collection of useful data regarding the income and output of nitrogen and other elements.

**Macroscopical Examination.** Among the macroscopical constituents of the feces may be mentioned the following: Intestinal parasites and their ova, undigested food particles, gallstones, pathological products of

<sup>2</sup> Lloyd and Crampton: *J. Nutrition*, **41**, 629 (1950); Irwin and Crampton: *Ibid.*, **43**, 77 (1951).

the intestinal wall, enteroliths, intestinal sand, and objects which have been accidentally swallowed.

**Microscopical Examination.** The fecal constituents which at various times and under different conditions may be detected by the use of the microscope are as follows: (1) Constituents derived from the food, such as muscle fibers, connective-tissue shreds, starch granules, and fat; (2) formed elements derived from the intestinal tract, such as epithelium, erythrocytes, and leukocytes; (3) mucus; (4) pus corpuscles; (5) parasites; and (6) bacteria. In addition to the constituents named, the following crystalline deposits occasionally may be detected: cholesterol, coprosterol, soaps, fatty acid, fat, hematin, "triple phosphate," Charcot-Leyden crystals (see Fig. 104), and the oxalate, carbonate, phosphate, sulfate, and lactate of calcium.

FIG. 104. CHARCOT-LEYDEN CRYSTALS.

**Fat in Feces.** The amount and composition of fat excreted by way of the feces is largely independent of food fat but tends to approximate the composition of blood lipides. Fecal fat is largely of endogenous origin, the secreted fat being partially reabsorbed; only to a minor degree does fecal fat come from epithelial debris and bacteria.

About one-third of the fat in normal feces is unsaponifiable. The coprosterol (also called coprostanol) of the feces is similar to cholesterol, and is formed by the reduction of the latter. It contains two more atoms of hydrogen than cholesterol and is thus a saturated alcohol  $C_{27}H_{47}OH$ . A small amount of cholestanol, an isomer of coprosterol, is also found in feces. It appears to be formed in the tissues and excreted in the bile. Except for the D vitamins, cholesterol is the only sterol absorbed from the intestine. The phytosterols of plants are not absorbed, being excreted in the feces. Coprosterol responds to cholesterol color tests and has the same solubility, but possesses a lower melting point and crystallizes as fine needles instead of plates such as cholesterol forms.

After the intravenous administration of cholesterol-4- $C^{14}$  to normal rats it was found<sup>3</sup> that from 10 to 14 per cent of the total  $C^{14}$  in bile and from 17 to 23 per cent of fecal  $C^{14}$  were recovered in the nonsaponifiable fraction. This includes cholesterol, dihydrocholesterol, coprosterol, etc. The fatty acid fraction contained little if any  $C^{14}$ . About 80 per cent of the fecal  $C^{14}$  and about 90 per cent of the bile  $C^{14}$  was present in the form of bile acids.

The fat content of normal feces may vary from 5 to 25 per cent (on a dry basis). Excessive excretion of fat via feces is known as steatorrhea, a condition due to failure to absorb fat as in enteritis, hepatic disorder, biliary obstruction, celiac disease, or sprue. Excreted fat is partly saponified and may entail loss of calcium, as soap, to the extent of producing pathological demineralization.

**Blood in Feces.** The detection of minute quantities of blood in the feces—so-called occult blood—is an aid to the correct diagnosis of certain disorders. In these instances the hemorrhage is ordinarily so slight that

<sup>3</sup> Siperstein, Jayko, Chaikoff and Dauben: *Proc. Soc. Exptl. Biol. Med.*, **81**, 720 (1952).

the identification by means of macroscopical characteristics as well as the microscopical identification through the detection of erythrocytes are both unsatisfactory in their results. Of the tests given for the detection of occult blood the benzidine reaction is probably the most satisfactory.<sup>4</sup> Since occult blood occurs with considerable regularity and frequency in gastrointestinal cancer and in gastric and duodenal ulcer, its detection in the feces is of especial value as an aid to a correct diagnosis of these disorders. Certain precautions are essential, such as the establishment of a meat-free diet over a period of time before the specimen is collected. (Feces from a meat diet will give an occult blood reaction with some of the most delicate tests.) Bleeding from the bowel such as is seen in hemorrhoids, as well as the admixture of menstrual blood, is to be considered in the interpretation of the result. After the ingestion of 50 ml. of human blood 85 to 95 per cent of the hemoglobin appears as protohemin in the feces.

**Bacteria in Feces.** It has been quite clearly shown that the intestine of the newly born is sterile. However, this condition is quickly altered, and bacteria may be present in the feces before or after the first ingestion of food. There are three possible means of infecting the intestine; i.e., by way of the mouth or anus or through the blood. The infection by means of the blood seldom occurs except under pathological conditions; thus the usual sources are limited to the mouth and anus.

In infants with pronounced constipation, two-thirds of the dry substance of the stools has been found to consist of bacteria. In the stools of normal adults probably about one-third of the dry substance is bacteria. The average excretion of dry bacteria in 24 hours for an adult is about 8 g. The output of fecal bacteria has been found to undergo a decrease under the influence of water-drinking with meals. There is also a decrease in intestinal putrefaction, a fact which indicates that at least a part of the bacterial deficit is made up of putrefactive organisms. In some cases, more than 50 per cent of the total nitrogen of feces has been shown to be bacterial nitrogen.

Some of the more important organisms met with in the feces are the following: *E. coli*, *B. lactis aerogenes*, *Cl. welchii*, *B. bifidus*, and *coccal* forms. Of these the first three types mentioned are gas-forming organisms. The production of gas by the fecal flora in dextrose bouillon is subject to great variations under pathological conditions; alterations in the diet of normal persons will also cause wide fluctuations. Data as to the production of gas are of considerable importance in a diagnostic way, although the exact cause of the variation is not yet established. It should be borne in mind in this connection that gas volumes are frequently variable with the same individual. For this reason it is necessary in every instance to follow the gas production for a considerable period of time before drawing conclusions.

After aureomycin therapy, coliform organisms entirely disappear from the feces, while the clostridia diminish in quantity and may even disappear. No appreciable influence on the fecal flora has been shown to

---

<sup>4</sup> Hughes: *Brit. Med. J.*, **2**, 970 (1952).

follow the parenteral administration of penicillin and dihydrostreptomycin in combination.

**Enzymes in Feces.** Various enzymes have been detected in the feces. The first one so demonstrated was pancreatic amylase. The amylase content of the feces has been considered to be an index of pancreatic activity. The excretion of this enzyme has been found to increase under the influence of water-drinking with meals. Other enzymes which have been found in the feces under various conditions are trypsin, rennin, maltase, sucrase, lactase, nuclease, and lipase. In an abnormally rapid transit of food through the intestinal tract, such as is seen in certain diarrheas, nearly all of these enzymes may be detected.

**Vitamins in Feces.** A variety of vitamins are present in normal feces. Their number and amount are subject to wide variation under pathological conditions. For example, the feces of enteritis patients have been found to be deficient in vitamins B<sub>1</sub> and B<sub>6</sub> (but not B<sub>2</sub>) compared with feces of normal persons.<sup>5</sup> Pennington<sup>6</sup> reports a heat-labile vitamin B<sub>12</sub> complex in feces of the rat.

**Fecal Nitrogen.** The nitrogen present in the feces exists principally in the form of (1) bacteria, (2) unabsorbed intestinal secretions and digestive juices, (3) epithelial cells, (4) mucous material, (5) food residues, and (6) amino acids. In the early days of nutrition study the fecal nitrogen was believed to consist principally of food residues. We now know that such residues ordinarily make up but a small part of the total nitrogen of the stools of normal individuals who exercise normal mastication. When meat has been bolted, however, from 0.5 to 16 g. of macroscopical meat residues have been found in a single stool. The phrase "metabolic-product nitrogen" has been used as a designation for all fecal nitrogen except that present as food residues and bacteria. Bacteria cannot logically be classed under metabolic nitrogen since they doubtless develop at the expense of food nitrogen as well as at the expense of that in the intestinal secretions. In the accurate study of protein utilization<sup>7</sup> a correction should be made for *metabolic nitrogen*. Data regarding the output of metabolic nitrogen may be secured by determining the fecal-nitrogen excretion on a diet of proper energy value but *containing no nitrogen*. However, to prevent tissue catabolism from exceeding its normal level, it is customary in studies of basal nitrogen metabolism to include a minimal percentage of adequate protein in the maintenance diet.

**Amino Acids in Feces.** Fecal amino acids are derived from protein digestion as well as from intestinal organisms and secretions. It has been shown<sup>8</sup> that excretion of free amino acids was more abundant in the feces of the breast-fed infant than in those of the artificially fed infant. The feces of the breast-fed infant showed alanine to be the predominant amino acid, whereas in the feces of the artificially fed baby valine and lysine predominated. In experiments on white rats it has been shown that fecal excretion of lysine, valine, histidine, and methionine is much higher on

<sup>5</sup> Diaz *et al.*: *Rev. clín. españ.*, **44**, 233 (1952).

<sup>6</sup> Pennington: *Biochem. J.*, **48**, xviii (1951).

<sup>8</sup> Ross: *Lancet*, **241**, 190 (1951).

diets supplying potato starch (either raw or autoclaved) or dextrin than on those containing sucrose or glucose.<sup>9</sup>

A method has been suggested for the determination of metabolic fecal phosphorus<sup>10</sup> excretion through the use of casein labeled with P<sup>32</sup>.

**Fasting Feces.** Feces are still excreted from the intestine even when no food is ingested. Carefully conducted fasting experiments have demonstrated this. A dog nourished on an ordinary diet to which bone ash has been added will excrete gray feces. When fasted, such an animal will after a few days excrete a small amount of a greenish-brown mass, containing no bone ash. These are fasting feces. They are of a pitchlike consistency and turn black on contact with the air. Adult fasting men have been found to excrete 7 to 8 g. of feces per day, the daily nitrogen value being about 0.1 g. No separating medium such as charcoal or carmine (p. 448) should be used in differentiating fasting feces.

**Examination for Clinical Purposes.** The examination of feces for evidences of parasitism (detection of parasites and their ova), such as hookworm, tapeworm, etc., is of considerable clinical importance. For diagnostic purposes the macroscopical and microscopical examinations of the feces ordinarily yield much more satisfactory data than are secured from its chemical examination. Possibly with the exception of certain examinations for occult blood, the most satisfactory data for diagnostic purposes are secured by microscopical examination. This presupposes a knowledge of microscopical technique and the use of certain microchemical tests, by which much information can be obtained. The principle underlying this examination consists in the study of the actual changes which the various foodstuffs have undergone during digestion. A knowledge of the changes which occur in normal digestion and which are seen in normal feces enables one readily to detect pathological variations. One diet widely used for this purpose is the Schmidt diet. The modification<sup>11</sup> described below is better adapted to American conditions.

### MODIFIED SCHMIDT DIET

#### *Breakfast:*

100 g. of farina or oatmeal  
60 g. of toast  
20 g. of butter  
250 ml. of milk

#### *Luncheon:*

Rice soup (chicken broth with rice)  
100 g. of green vegetable (asparagus)  
100 g. of mashed potato  
60 g. of toast  
20 g. of butter  
250 ml. of milk

#### *4 o'clock:*

250 ml. of milk

#### *Dinner:*

150 g. of chopped meat, grilled on the outside and rare in the center  
100 g. of green vegetable (spinach)  
100 g. of mashed potato  
60 g. of toast  
20 g. of butter  
250 ml. of milk  
Stewed fruit

## EXPERIMENTS ON FECES

**1. Collection and Preservation of Feces** (see also Chapter 33). Friction-top tin cans may be prepared for the collection of stools by adding a few drops of

<sup>9</sup> Harper, Katayama, and Jelinek: *Can. J. Med. Sci.*, **30**, 578 (1952).

<sup>10</sup> Lofgreen, Kleiber, and Quick: *J. Nutrition*, **47**, 571 (1952).

<sup>11</sup> Used by Dr. Martin E. Reh fuss of Philadelphia.

formalin or alcoholic solution of thymol (from which the alcohol may be evaporated by warming). Stools may be dried directly in these cans. If glass containers are preferred, pyrex pots with glass lids may be used. To prevent loss of nitrogen sufficient sulfuric acid should be added to render the fecal mixture strongly acid. The contents may be dried on a steam bath in a hood and the residue weighed and powdered for sampling. If nitrogen or mineral analyses are to be conducted, the fresh stools may be mixed with 100 to 200 ml. of water and an equal volume of concentrated  $\text{H}_2\text{SO}_4$  gradually added while stirring. The homogenized suspension thus collected and preserved throughout the 24 hours may be diluted to volume and an aliquot taken for analysis.

**2. Macroscopical Examination.** If the stool is watery pour it into a shallow dish and examine directly. If it is firm or pasty it should be treated with water and carefully stirred before the examination for macroscopical constituents is attempted. The macroscopical constituents may be collected very satisfactorily by means of a double layer of cheesecloth or a sieve of fine mesh.

**3. Reaction.** Thoroughly mix the feces and apply moist indicator papers to the surface. If the stool is hard it should be mixed with water before the reaction is taken. Examine the stool as soon after defecation as is convenient, since the reaction may change very rapidly. The reaction of the normal stools of adult man is ordinarily neutral or faintly alkaline to litmus, but seldom acid. Infants' stools are generally acid in reaction. The glass electrode is useful in determining fecal pH since it is not affected by reducing substances commonly present, nor by the presence of solids.

**4. Starch.** If any imperfectly cooked starch-containing food has been ingested, it will be possible to detect starch granules by a microscopical examination of the feces. If the granules are not detected by a microscopical examination, the feces should be placed in an evaporating dish or casserole and boiled with water for a few minutes. Filter and test the filtrate by the iodine test in the usual way (see p. 84).

**5. Blood.** Undecomposed blood may be detected macroscopically. If uncertain, look for erythrocytes under the microscope, and spectroscopically for the spectrum of oxyhemoglobin (see p. 492).

In case the blood has been altered or is present in minute amount (occult blood) and cannot be detected by the means just mentioned, the following tests may be tried:

**BENZIDINE REACTION.** (a) Make a thin fecal suspension using about 5 ml. of distilled water. Shake with 5 ml. of ether to remove the fat and discard this ether extract. Acidify the residue with acetic acid and extract again with 5 ml. of ether. Pour the acid ether extract into a small evaporating dish. Evaporate to dryness on a hot water bath (with flame turned out). Add a few drops of water, a drop of saturated solution of benzidine in glacial acetic acid and a drop of 3 per cent hydrogen peroxide. A blue or green color indicates the presence of blood.

(b) **SLIDE MODIFICATION.** Take up a little of the solid stool on a match, smear it on an object glass, and pour the reagent over it. If there is blood present the smear turns blue and there is no misleading green tint from fluid. Make the solution as follows: Add a knife-tip of benzidine to 2 ml. of glacial acetic acid, and add 20 drops of a 3 per cent solution of hydrogen peroxide.

By this dry technique there is no danger of soiling the fingers, and the test is more sensitive than the usual wet benzdine test. The smear of stool is either blue or it is not blue. The rapidity of the color change gives some idea as to the proportion of blood in the stool; with much blood present the change to blue is instantaneous.

(c) LEVIN-WATT MODIFICATION.<sup>12</sup> Emulsify a small portion of feces in distilled water. Filter into a clean test tube, using a Whatman No. 5 or a more retentive filter paper. Treat 3 ml. of the filtrate with 8 drops of 50 per cent acetic acid or glacial acetic acid, and mix. Add 8 drops of hydrogen peroxide (C.P. 3 per cent) to the mixture and shake. Make a contact ring by carefully overlaying final mixture drop by drop with an alcoholic benzdine solution.<sup>13</sup> Tilt the test tube in order to bring about slight mixing at the ring. A green color at the area of contact indicates a positive reaction. The intensity of color varies with the concentration of blood.

**6. Quantitative Determination of Fat in Feces: Principle.** The determination of fat in dried feces is a more or less tedious process, and one which is somewhat inaccurate if applied to pathological feces. Most of the methods for the determination of fat in the moist feces are accurate, but require a long time. Saxon has proposed a method for the determination of fat in moist feces, which is speedy, convenient, and accurate. The soaps of the feces are converted into free fatty acids by means of hydrochloric acid, and the material is then extracted by shaking with ether. The ether removes the neutral fat, the fatty acids which were present as such, the fatty acids derived from the soaps, and the cholesterol. The ether is removed by distillation, the crude fat purified by means of petroleum ether, and the weight of the total fat obtained. The fat is then dissolved in benzene and titrated with tenth-normal sodium alcoholate solution, using phenolphthalein as an indicator. The fatty acid is calculated, from the titration, as stearic acid.

**Procedure.** Place about 5 g. (accurately weighed) of the thoroughly mixed feces in a 100-ml. glass-stoppered graduated cylinder.<sup>14</sup>

Add 20 ml. of distilled water, 1 to 2.5 ml. of concentrated hydrochloric acid (depending upon the amount of the sample), and, again, sufficient distilled water to make a total volume of 30 ml. Add exactly 20 ml. of ether, stopper, and shake vigorously for five minutes. Allow to stand for a few seconds, remove the stopper, add exactly 20 ml. of 95 per cent alcohol, and again shake for five minutes.

Set the cylinder aside. The ether, containing practically all of the fat, will come to the top as a colored transparent layer. Draw the ether layer off into a tall 150- to 200-ml. beaker. The thin layer of ether which remains is diluted with 5 ml. of ether, the tube slightly agitated, and the ether drawn off. This is done in all five times, care being taken each time to wash down the sides of the cylinder. The stopper should also be washed. 20 ml. of ether are

<sup>12</sup> Levin and Watt: *Rev. Gastroenterol.*, **16**, 650 (1949).

<sup>13</sup> Dissolve 6 g. of benzdine in 100 ml. of 95 per cent ethyl alcohol. It is preferable to use a solution which is 2 to 3 days old.

<sup>14</sup> Care must be taken not to smear the neck of the cylinder. This may be avoided by removing the feces from the weighing bottle by means of a glass rod, the end of which is flattened and bent in the shape of a hoe, and transferring small bits of the feces from the hoe to the cylinder on short pieces of glass rod which are dropped into the cylinder together with the feces. Tests made in the senior author's laboratory have shown that the fat of feces decreases on standing even in the frozen condition. Analyses should be made on fresh feces.

again added, and the cylinder shaken for five minutes and set aside. When the ether has nearly stratified, draw it off and wash as before. During the second washing, stratification will complete itself. Evaporate the ether<sup>15</sup> until no trace of the alcohol which has been carried over with it remains. To the residue add 30 ml. of low-boiling petroleum ether (it should boil below 60° C.), and allow to stand over night. Petroleum ether for this work should be frequently tested for a residue on evaporation. If a residue is left, the ether should be redistilled. Filter the petroleum ether solution of the fat, catch the filtrate and washings in a tall, weighed, 100-ml. beaker, evaporate off the solvent, dry at 90° C., desiccate, and weigh. After weighing, dissolve the contents of the beaker in 50 ml. of benzol, heat almost to the boiling point, add 2 drops of a 0.5 per cent solution of phenolphthalein, and titrate with a decinormal solution of sodium alcoholate.<sup>16</sup>

CALCULATIONS. The weight of total fat is obtained by subtracting the weight of the empty beaker from the weight of the beaker plus the dried fat. The weight of fatty acids (in terms of mg. of stearic acid) is obtained by multiplying the number of ml. of decinormal sodium alcoholate solution by the factor 28.4. The difference between the weight of total fat and the weight of fatty acids is the weight of neutral fat in the sample extracted.

A separate determination without the addition of hydrochloric acid may be run upon the sample, for the purpose of determining the weight of neutral fat and free fatty acids. The difference between this weight and the weight of total fat is the weight of fatty acid present in the original sample in the form of soaps.

# Blood, Lymph, and Cerebrospinal Fluid

**General.** Blood serves as the principal transport system of the body, the heart furnishing the propulsive force. The most important quantitative functions of the blood are to bring oxygen and nutrients to the tissues and to carry away the waste products and deliver them to the excretory organs—the kidneys, lungs, biliary system of the liver, intestinal mucosa, and skin. Blood also plays an important role in coordinating the activities of various tissues through distribution of hormones, in maintaining the pH and the oxidation-reduction potential within narrow limits, in controlling temperature, osmotic pressure, and ionic concentration, in supplying defense against infection, and in guarding against hemorrhage.

The blood makes up about 5 to 7 per cent of the body weight in man, or approximately 2 to 3 liters per sq. m. of body surface, being more nearly proportional to the latter than to weight. Lower relative volumes of blood are observed in obese than in thin individuals. The volume of the circulating blood in a normal individual is maintained within rather narrow limits; any marked change in blood volume, as by sudden severe hemorrhage, etc., has serious consequences and may even result in death. Blood volume may be measured by the addition to the blood of a known amount of a readily detectable and nondiffusible substance, such as certain dyes, hemoglobin derivatives, and radioactive compounds; the extent to which the substance is diluted by the blood is a measure of the total blood volume.

**Composition of Blood.** Since blood has numerous functions, its composition is necessarily complex. The general composition is summarized in the following table:

- I. Cellular fraction
  - Volume: 45 per cent
  - Constituent cells
    - 1. Erythrocytes (5,000,000 per cmm.)
    - 2. Leukocytes (6,000 per cmm.)
    - 3. Platelets (250,000 per cmm.)
- II. Plasma fraction
  - Volume: 55 per cent
  - A. Nondiffusible constituents
    - 1. Albumins
    - 2. Globulins
    - 3. Fibrinogen
    - 4. Enzymes, lipides, etc.

## B. Diffusible constituents

1. Catabolic products: urea, creatinine, uric acid, etc.
2. Anabolic constituents: glucose, amino acids, creatine, etc.
3. Electrolytes:  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{++}$ ,  $\text{Mg}^{++}$ ,  $\text{Cl}^-$ ,  $\text{HCO}_3^-$ ,  $\text{HPO}_4^-$ ,  $\text{H}_2\text{PO}_4^-$ , etc.
4. Hormones, vitamins, etc.

The specific gravity of whole blood is about 1.060; that of plasma is approximately 1.026. Since the cells are heavier, they can be separated from plasma by centrifugation. The pH averages 7.4; the viscosity 1.7 to 2 (water = 1), the freezing point  $-0.56^\circ \text{C}$ . and the total osmotic pressure at  $37^\circ \text{C}$ . is 7.6 atmospheres.

**Blood Plasma and Serum.** When plasma is obtained without the addition of an anticoagulant, it is called *native*. Such a plasma, if kept from having contact with a wettable surface and covered with mineral oil to delay the escape of carbon dioxide, retains fairly closely its *in vivo* state and composition. For the usual chemical analysis, plasma obtained by the addition of sodium oxalate to prevent clotting is generally suitable and is commonly employed.

Serum is the fluid obtained when blood clots. It is similar to plasma in composition but lacks fibrinogen and has a diminished concentration of other clotting factors such as prothrombin. Serum is preferable to plasma for the determination of calcium, albumin, and globulin.

The plasma contains about 91 to 92 per cent of water and about 8 to 9 per cent of solid matter, of which about 7 per cent, or more than 85 per cent of the total solids, is protein.

**Plasma Proteins.** The plasma proteins represent a complex mixture containing a number of components which differ in properties and function. The major component proteins of plasma include (1) fibrinogen, (2) the various globulins, and (3) the albumins; (4) nucleoprotein and (5) seromucoid are also present in limited amounts.

**FIBRINOGEN.** The fibrinogen of normal human plasma is present in a concentration of about 0.19 to 0.33 g. per 100 ml. of plasma. The average in the Red Cross series was 0.28 g. per 100 ml. Fibrinogen is likewise found in lymph and chyle as well as in certain exudates and transudates. Human blood fibrinogen is said to have a molecular weight of approximately 500,000, although research suggests that it may be as low as 350,000. The molecule is highly elongated, with a length estimated to be from 600 to 700 Ångstrom units and with an axial ratio of about 20 to 1. The amino acid composition is given in Chapter 4. Fibrinogen is insoluble in salt-free water but is soluble in dilute salt solutions. It is the most readily precipitable of all the common blood proteins by concentrated salt solutions, being precipitated upon half-saturation with sodium chloride or 20 per cent saturation with ammonium sulfate. The coagulation temperature of fibrinogen is about  $55^\circ \text{C}$ . in neutral solutions.

Fibrinogen is unique among the blood proteins in that it is readily converted into insoluble fibrin by the action of the enzyme thrombin. Research has contributed to the elucidation of the mechanism of this

reaction.<sup>1</sup> Apparently when thrombin acts on fibrinogen, a fibrino-peptide is split off and the remaining molecule becomes activated. It polymerizes to form fibrin, which separates as simple and compound fibers which interestingly exhibit cross-striations with a constant periodicity.<sup>2</sup> The fibrin fibers form a meshwork or reticulum which constitutes the framework of the clot. On standing, the clot shrinks, thereby expressing clear serum. This phenomenon, which is called clot retraction, depends on the presence of intact platelets which adhere to the fibrin strands and are in some way responsible for condensing the fibrin mass.

ALBUMINS AND GLOBULINS. The bulk of the plasma proteins consists of the albumin and globulin fractions. The albumin fraction ordinarily preponderates, comprising well over one-half of the total protein of normal human plasma, but this relation may be altered or even reversed in disease. As a class the plasma albumins differ from the globulins in having a greater solubility, a lower molecular weight, and a more acid isoelectric point. Human serum albumin, for example, has a molecular weight of 69,000 and an isoelectric point at pH 5.4, while the  $\gamma$ -globulin of serum (see p. 463) has a molecular weight of 156,000 and an isoelectric point at pH 6.5. Marked differences in amino acid composition between albumins and globulins have been established, as is evident from the data of the table on p. 122 in Chapter 4, but these differences, while significant from an analytical point of view, as yet have not been related to differences in either structure or function.

The albumin fraction of the plasma is relatively homogeneous and well characterized; a number of serum albumins from various sources have been obtained in crystalline form. Some of these crystalline proteins appear to contain carbohydrate as an integral portion of the molecule.

The globulin fraction on the other hand appears to consist of a variety of proteins of somewhat similar general characteristics, but which by suitable means may be further fractionated into a number of components. Although relatively homogeneous fractions of the plasma globulins have been obtained, none of these proteins has as yet been crystallized. From the point of view of solubility, two general types of globulin are recognized, *euglobulin* and *pseudoglobulin*.

Euglobulin is a true globulin in that it is insoluble in salt-free water; pseudoglobulin, while possessing the general properties of the globulins, is soluble in salt-free water. This distinction between two types of globulins, while useful, is by no means well defined. The extensive studies of Sørensen on this subject, already referred to in Chapter 5, have led him to postulate that the globulin fraction of serum represents a loose combination of euglobulin and pseudoglobulin of the type  $E_pP_q$ , in which E and P represent euglobulin and pseudoglobulin complexes respectively, combined in the relative proportions of  $p$  and  $q$ . Fractionation by various means results in a shift in the proportions of E and P with the resultant formation of more soluble and less soluble complexes. Sørensen was unable to prepare a sample of either euglobulin or pseudoglobulin which was

<sup>1</sup> Lorand: *Nature*, 167, 992 (1951); Laskowski, Rakowitz, and Sheraga: *J. Am. Chem. Soc.*, 74, 28 (1952).

<sup>2</sup> Hawn and Porter: *J. Exp. Med.*, 86, 285 (1947).

entirely free of the other protein. Cohn, McMeekin, *et al.*, have likewise shown<sup>3</sup> that the euglobulin fraction of serum protein (i.e., globulin precipitated by dialysis) is considerably increased in amount over that first obtained by ammonium sulfate fractionation if the precipitated protein is freed from the last traces of salt by electro dialysis and if the solubility is not influenced by the presence of other proteins.

**Fractionation of the Plasma Proteins.** The separation and characterization of the individual protein components of the plasma is of considerable importance. It facilitates study of the chemical nature and physiological function of each protein and of the significance of variation in the protein composition of the plasma in health and disease. It likewise leads to the possibility of the commercial preparation, from human or animal plasma, of purified preparations of the individual proteins for laboratory, clinical, and industrial use.

Methods for separating the plasma proteins from one another are based almost entirely upon (1) differences in physical properties, such as solubility in water, concentrated salt solutions, and other solvents; (2) rate of sedimentation in the ultracentrifuge; and (3) rate of electrophoretic migration. The various plasma proteins do not differ sufficiently in chemical composition or behavior to permit their separation at the present time on a purely chemical basis. Immunological means of separation—i.e., the use of precipitins (cf. Chapter 5)—specific for the individual protein, have certain disadvantages and have been little used.

**DIFFERENCES IN PHYSICAL PROPERTIES.** The type of fractionation obtained by differences in solubility in water and in concentrated salt solutions is illustrated in the following table which has been adapted from the work of various investigators.<sup>4</sup> The salts listed in the table,

FRACTIONATION OF THE PLASMA PROTEINS BY CONCENTRATED SALT SOLUTIONS

ammonium sulfate and sodium sulfate, are those most commonly employed; sodium chloride, magnesium sulfate, and sodium or potassium phosphate may also be used under suitable conditions. It will be seen

<sup>3</sup> Cohn, McMeekin, Oncley, Newell, and Hughes: *J. Am. Chem. Soc.*, **62**, 3386 (1940).

<sup>4</sup> Howe: *J. Biol. Chem.*, **49**, 109 (1921); Gutman, Moore, Gutman, McClellan, and Kabat: *J. Clin. Invest.*, **20**, 765 (1941); and others.

that as the concentration of salt is progressively increased, the various fractions become insoluble and will precipitate from solution. Fibrinogen, which is sometimes classified as a globulin because of its solubility characteristics, is the least soluble protein, followed by euglobulin, the pseudoglobulins, and albumin. It is usually considered that *all* the globulins of plasma are precipitated upon half-saturation with ammonium sulfate, or by a 22 per cent concentration of sodium sulfate at 37° C., and that the protein remaining in solution is albumin. This is the common analytical basis for separation of the albumin and globulin fractions of plasma prior to their analytical estimation.

The fractionation represented in the table above must be regarded as being quite arbitrary. The precipitation limits are not sharply defined, as might be inferred from the table, but rather represent arbitrarily established limits which in reality correspond to zones, between which there is no well-defined transition. The quantitative values given in the table are therefore characteristic of this particular type of fractionation only, and should not be expected to agree with values obtained by fractionation by other methods. Despite this limitation, the method has proved of value in many studies on the variation in plasma protein fractions in health and disease.

Fractionation of the plasma proteins by various concentrations of aqueous alcohol is described by Cohn, Luetscher, *et al.*<sup>5</sup> While alcohol denatures proteins readily at room temperature, denaturation does not occur at temperature ranges of 0° to -5° C., and satisfactory fractionation of the general nature of that obtained by the use of concentrated salt solutions is obtained. The advantage of alcohol fractionation appears to lie chiefly in the ease with which the fractionating agent may be removed from the protein, along with water, in the process of preparing stable dried preparations of the various fractions (lyophilization), thus rendering the method applicable to the large-scale preparation of such dry protein fractions for clinical and industrial use.

By means of varying the temperature, the alcohol concentration, and the pH, Cohn and associate were able to separate the plasma proteins into six fractions which they designated by Roman numerals. Thus Fraction I, which contains most of the fibrinogen as well as a high concentration of the factor which is deficient in hemophilia, is obtained at -3° C. with 8 to 10 per cent alcohol at pH 7.2. To obtain the other fractions, the alcoholic concentration is progressively increased and the pH is lowered. Of particular clinical importance is Fraction V which contains nearly all of the albumin. None of the fractions, however, contain pure components. Most of the  $\gamma$ -globulin is distributed between Fractions II and III. This globulin furnishes definite protection against the paralytic effects of poliomyelitis.

The low-temperature alcohol method was supposed to yield native serum proteins. Unfortunately, even though the albumins were still soluble at the isoelectric point they were denatured to the extent that they were poorly metabolized by the organism when injected. The low-

---

<sup>5</sup> Cohn, Luetscher, Oncley, Armstrong, and Davis: *J. Am. Chem. Soc.*, **62**, 3396 (1940).

temperature alcohol method has therefore been supplanted by a procedure involving the use of specific adsorbants and fractional precipitation with zinc salts at pH 7.4. The  $Zn^{++}$  ions are removed by means of a cation exchange resin. The following components have been identified in the fractions obtained in this method:

| <i>On Cation-Exchange Resin</i>                                            | <i>On Stroma of Red Cells</i> | <i>Precipitate with <math>Zn^{++}</math> at pH 7.4</i>                                         | <i>Filtrate from Zinc at pH 7.4</i>                                                              |

The serum albumin fraction so prepared is relatively heat-stable, does not contain any known virus contaminants, and is approximately as active osmotically as untreated human plasma.

USE OF THE ULTRACENTRIFUGE. Separation of the plasma proteins in the ultracentrifuge of Svedberg (see Chapter 1) has had somewhat limited applicability because of the superiority of other available methods, but has yielded valuable theoretical information. It has been found that bovine serum contains an albumin with a molecular weight of about 64,500 as estimated from the sedimentation data, together with several globulins. The two most abundant globulins have molecular weights of about 165,000.

ELECTROPHORESIS. The fractionation of the plasma proteins by the use of electrophoresis (see Chapter 1) was initiated largely by the pioneer work of Tiselius. In the electrophoretic separation of the plasma proteins, advantage is taken of the differences in mobility of the various protein ions present under the influence of a potential gradient. The protein solution is first dialyzed against a suitable buffer solution through cellophane tubing (Visking sausage casing) in order to equilibrate the two solutions with regard to their pH and conductivity. In an electrophoresis cell of the type shown in Fig. 105, one of the rectangular limbs and the bottom section are filled with the protein solution, while the other limb and the rest of the electrophoresis cell including the electrode vessels (not shown in the figure) are filled with the buffer solution serving as the outside fluid during dialysis. Sharp starting boundaries are produced by manipulating the cell sections. Reversible electrodes of the silver-silver chloride type, immersed in strong KCl solution, are connected with a suitable source of

FIG. 105. TYPE OF CELL USED FOR ELECTROPHORESIS STUDIES ON PLASMA PROTEINS.  
Courtesy, Klett Manufacturing Co., New York.

high-voltage direct current. Under the influence of the potential gradient thus produced (4 to 8 volts per cm.) the various species of protein ions present migrate downward in one limb of the cell and upward in the other, in the direction toward the anode at alkaline pH values, at a rate which is a function of the surface-charge density, i.e., the number of free positive (or negative) charges per area unit of the surface of the protein molecules. By so moving, the individual protein ion species form more or less well-defined boundaries arranged in the order of their respective electrophoretic mobilities. However, it is to be noted that there is a considerable amount of overlapping of the various protein regions so that

FIG. 106. ELECTROPHORETIC PATTERNS OF BLOOD PLASMA FROM VARIOUS ANIMAL SPECIES.

Courtesy, Deutsch and Goodloe, *J. Biol. Chem.*, **161**, 1 (1945).

only the *fastest* and the *slowest* components in a multicomponent system may, as a rule, be obtained in pure form by means of the moving-boundary technique. As the concentration of the individual proteins changes, the index of refraction of the medium likewise changes, and by suitable optical methods based upon this principle the migration of the various protein fractions may be followed (Longsworth, Svensson).

The type of pattern obtained during electrophoresis of a mixture of components is illustrated by Fig. 106, which represents the electrophoretic patterns of various animal plasmas. The distance along the  $x$  axis is a measure of the relative velocity of movement of the various ion species present, and the height of the peaks corresponds to the difference in refractive index between the moving boundary and the adjacent fluid, the area under each curve being proportional to the amount of material present moving with an average velocity represented by the

position of the peak along the  $x$  axis. Thus by this method it is possible not only to distinguish between ion species of different mobilities but also to estimate the relative amounts of each type of ion present.

Tiselius demonstrated that normal plasma contained at least five electrophoretically distinguishable components, which were identifiable as albumin, fibrinogen, and three globulins, designated  $\alpha$ -,  $\beta$ -, and  $\gamma$ -globulin respectively, the  $\alpha$ -globulin having the fastest velocity in the globulin group and the  $\gamma$ -globulin the slowest. From electrophoretic data, it is clear that while albumin and fibrinogen are reasonably homogeneous—the high sharp peak corresponds to a migration of protein ions the majority of which have the same net charge and weight—the globulin fraction consists of a number of types of ions which may be classed roughly into three groups but obviously include ion species of quite varying mobilities within any one group. Indeed, later workers have been able to show that the three globulin fractions of Tiselius may be resolved into further components which have been designated  $\alpha_1$ - and  $\alpha_2$ -globulin,  $\beta_1$ - and  $\beta_2$ -globulin, etc. In addition, stationary peaks, designated as  $\delta$  and  $\epsilon$  respectively, are observed in the ascending and descending boundary diagrams (see Fig. 106). These have been shown to represent boundary anomalies rather than additional protein components. The fibrinogen boundary, usually designated by the symbol  $\phi$ , is situated between the  $\beta$ - and  $\gamma$ -globulin boundaries. Following the example of Longsworth, most workers employ a diethylbarbituric acid-sodium diethylbarbiturate buffer system of pH 8.6 and 0.1 ionic strength which yields the highest degree of resolution of human serum or plasma diagrams.

The type of quantitative distribution of the plasma proteins that is obtained by electrophoresis is illustrated in the table below:

DISTRIBUTION OF PROTEINS IN CITRATED PLASMA AS DETERMINED BY ELECTROPHORETIC ANALYSIS\*

|                         | <i>Grams per<br/>100 ml. of<br/>Plasma</i> | <i>Per Cent of<br/>Total Protein</i> |
|-------------------------|--------------------------------------------|--------------------------------------|
| Total protein.....      | 6.03                                       | 100                                  |
| Albumin.....            | 3.32                                       | 55                                   |
| $\alpha$ -Globulin..... | 0.84                                       | 14                                   |
| $\beta$ -Globulin.....  | 0.78                                       | 13                                   |
| $\gamma$ -Globulin..... | 0.66                                       | 11                                   |
| Fibrinogen.....         | 0.43                                       | 7                                    |

\* Adapted from data of Cohn, Oncley, *et al.*: *J. Clin. Invest.*, **23**, 417 (1944).

It is to be noted that the three main globulin components are here present in approximately the same concentration, and furthermore that the ratio of albumin to globulin (the so-called “A/G ratio”) is 1.45. This value is to be contrasted with the value of approximately 2.0 or higher which is accepted as normal for fractionation by sodium sulfate precipitation.

There is no simple relation between the fractions of the plasma proteins

obtained by salting out and those obtained by electrophoresis studies. Thus Cohn, McMeekin, *et al.* (*loc. cit.*) have reported that at 34 per cent saturation with ammonium sulfate, the protein fraction precipitating consisted largely of  $\gamma$ -globulin, one-third of which was euglobulin—i.e., precipitated on dialysis. At 40 per cent saturation with ammonium sulfate the fraction contained  $\alpha$ - and  $\beta$ -globulins as well as some  $\gamma$ -globulin. This fraction likewise contained about one-third euglobulin. Increasing the saturation to 50 per cent yielded a precipitate which was free from  $\gamma$ -globulin but which contained both  $\alpha$ - and  $\beta$ -globulins, with only a few per cent of the fraction insoluble in water. Thus the two methods of fractionation—salting out and electrophoresis—yield overlapping results and are not directly comparable. But it is to be noted that by suitable salting-out methods fractions can be prepared which are homogeneous electrophoretically and which correspond to the fractions obtained electrophoretically. Thus Pillemer and Hutchinson<sup>6</sup> have reported that at 0° C. and pH 6.7 to 6.9, fractionation of human serum proteins with 42.5 per cent methanol yields A/G ratios which compare favorably with those obtained by electrophoretic analysis.

Recently, methods for the separation of small amounts of proteins, e.g., serum or plasma, by electrophoresis in filter-paper strips (zone electrophoresis) have been developed by Durrum, Grassmann, Tiselius, and others. This technique, though not as strictly quantitative as the classical moving-boundary method of electrophoresis, promises to have widespread application in clinical routine work. Fig. 57 (p. 184) shows the photograph of a developed paper strip after serum electrophoresis and the corresponding curve obtained by photoelectric densitometry of the stained protein bands. It should be pointed out that in zone or paper electrophoresis the individual bands visible after treating the fixed strip with suitable stains—e.g., Amido Schwarz 10B—contain the actual protein components rather than represent their boundary against zones of different refractive index as in the moving-boundary method of electrophoresis (compare with diagrams in Fig. 106).

At the present time it would appear that the electrophoretic method of analysis of the plasma proteins has its greatest value in studying the relative amounts of the various components present and the changes which these components undergo during disease, with a view to possible aid in diagnosis; but fractional precipitation is of value in the large-scale preparation of the individual components for industrial or clinical use, the purity of the fractions being controlled by electrophoretic analysis.

**Origin of the Plasma Proteins.** The liver is usually considered to be the site of formation of the plasma proteins, although other parts of the body may also have a function in this connection. Fibrinogen synthesis appears to be dependent entirely upon the liver. When the liver is damaged experimentally by poisons, the fibrinogen content of the blood falls, returning to normal with liver regeneration and repair. If the blood of a normal animal is removed as much as possible and replaced by defibrin-

---

<sup>6</sup> Pillemer and Hutchinson: *J. Biol. Chem.*, 158, 299 (1945).

ated blood, the fibrinogen level is restored to normal in a few hours; in the hepatectomized animal this restoration does not occur.

Evidence relating the liver to the production of the other proteins of plasma is less definite. Liver atrophy is frequently found in experimental and clinical hypoproteinemia. Since the albumin fraction appears to suffer most under these conditions, it would appear that the liver is associated with albumin synthesis, and furthermore that the factors controlling the synthesis of albumin are different from those for globulin; indeed, there is considerable evidence that parts of the body other than the liver are concerned with plasma globulin formation.

The study of plasma protein production in experimental animals is facilitated by the use of the experimental technique known as plasmapheresis, in which whole blood is removed from an animal, the blood cells separated from the plasma and resuspended in a suitable isotonic protein-free medium, and returned to the animal's circulation. Thus a plasma-protein deficit is produced which may be maintained at any desired point, and the extent to which the animal attempts to restore the plasma-protein level to normal may be used as an index of plasma-protein formation under various experimental conditions. Using this technique, for example, it has been found that plasma protein production in the dog may be maintained at normal levels for many weeks by the intravenous administration of a mixture of purified amino acids as the sole source of dietary nitrogen, and that those amino acids in particular which have been found by Rose to be essential in the diet of the young growing rat (see Chapter 33) are likewise significant in the production of plasma protein in the dog.

There is increasing evidence that the plasma proteins are in continuous metabolic equilibrium with other proteins and amino acids of the body. This view, first postulated by Whipple and collaborators as the result of studies on protein regeneration in animals by the plasmapheresis technique, is supported by the work of Schoenheimer *et al.*,<sup>7</sup> using the nitrogen isotope  $N^{15}$ . When amino acids containing this isotope were fed to rats in nitrogen equilibrium, both the tissue proteins and the plasma proteins were found to incorporate the isotopic nitrogen rapidly and at about the same rate. On discontinuing isotope administration, the isotope gradually disappeared from the plasma proteins, the estimated half life of the plasma-protein molecule being about two weeks. These and other experiments indicate that the plasma proteins in an animal are not static but are subject to continuous influence by dietary and metabolic factors.

**Functions of the Plasma Proteins.** In addition to the specific physiological function of certain of the plasma proteins, such as the role of fibrinogen and prothrombin in blood-clotting and the role of the plasma globulins in immunological reactions, certain general functions of the plasma proteins are recognized. These may be classified as nutritive and physicochemical.

---

<sup>7</sup> Schoenheimer, Ratner, Rittenberg, and Heidelberger: *J. Biol. Chem.*, **144**, 541, 545 (1942).

**NUTRITIVE FUNCTION.** The nutritive function of the plasma proteins has been definitely established largely through the work of Whipple and his associates. They have shown that the nitrogen (and protein) requirements of the fasting animal can be adequately supplied by the intravenous injection of plasma protein. Since this injected protein disappears from the circulation in a short time, it is presumably metabolized. Analyses of urinary nitrogen excretion after plasma-protein injection indicate an increased catabolism of protein. Whether this means that the plasma proteins are directly utilized metabolically or are first converted into tissue protein is not known; such a distinction would appear to be relatively unimportant in view of the existence of such a dynamic equilibrium between tissue proteins and plasma proteins as has already been postulated.

**PHYSICOCHEMICAL FUNCTIONS.** The physicochemical functions of the plasma proteins are equally important. Chief of these appear to be to aid in the maintenance of a normal blood volume and in the maintenance of a normal water content in the tissue fluids. By virtue of their colloidal dimensions the plasma proteins cannot normally diffuse through the blood capillary membranes into the relatively protein-free tissue fluids. They thus exert an osmotic pressure which acts as a force tending to hold a certain volume of water within the blood. This colloidal osmotic pressure—or *oncotic pressure*, as it is sometimes called—has a magnitude of about 25 mm. Hg. Although this is much less than 1 per cent of the total osmotic pressure of the plasma, nevertheless it becomes the dominant osmotic force in the blood capillaries, since the other plasma constituents are freely diffusible across the capillary membranes.

Of the various plasma proteins, albumin is by far the most significant in connection with osmotic pressure, being estimated to account for about 80 per cent of the total osmotic pressure of the plasma proteins. Gram for gram, albumin is at least twice as effective osmotically as globulin, largely because of its relatively lower molecular weight. It has been shown that 1 g. of plasma albumin is responsible for the retention of roughly 20 ml. of water in the blood. A loss of plasma protein, and particularly of plasma albumin, therefore leads to a diminished blood volume, and this is presumably a major cause of the symptoms of hemorrhagic shock. The administration of plasma protein, especially plasma albumin concentrates, has been shown to be of considerable value in both experimental and clinical shock.

The colloidal osmotic pressure of the plasma proteins is opposed by the filtering force of the blood pressure, which tends to drive water and dissolved substances across the capillary membranes into the tissue fluids. At the arterial end of a blood capillary, the blood pressure exceeds the colloidal osmotic pressure, and fluid is forced from the blood into the tissues; at the venous end the reverse action takes place, fluid entering the blood from the tissues. Normally there is a balance between these two opposing forces, and fluid distribution between the blood and tissues is normal. If this balance is upset by such conditions as a low plasma-protein content or an increased permeability of the capillary walls to protein, excessive amounts of water will accumulate in the tissues

(edema). A plasma-protein deficit is therefore an important (although by no means the only) cause of edema. Edema due to plasma-protein deficit has been successfully treated by measures which restore the plasma-protein level to normal.

A second physicochemical function of the plasma proteins is in connection with acid-base balance. Because the plasma proteins in solution at pH 7.4 are on the alkaline side of their isoelectric points, they exist to a certain extent as alkali salts. They thus act similarly to the alkali bicarbonate of the blood in furnishing base for the neutralization of acid, and indeed it has been shown that in the plasma the proteins are second to bicarbonate in importance in this respect.

Other functions of the plasma proteins are also recognized. They aid in promoting the mobility of the corpuscles, since red cells settle more rapidly in plasma than in protein-free isotonic solutions. The globulin fraction appears to be the carrier of the immune substances of the blood, and indeed the isolation and concentration of immune substances from human plasma is an important phase of fractionating the plasma proteins. The plasma proteins also combine with certain drugs and have thus been ascribed a vehicular function, although the precise significance of this property is not yet known.

**The Erythrocytes.** The erythrocytes or red cells make up about 45 per cent by volume of the blood. Variations from this value are frequently encountered; they are associated with changes in either the number of cells per unit volume of blood, or the size of the individual cells, or both. The relative cell volume of blood is determined with the hematocrit, a graduated tube which may be filled with whole blood and centrifuged. The volume of packed cells relative to the initial volume of blood is a measure of the cell volume. The top layer of packed cells is frequently almost colorless because of the predominance of leukocytes, which are not so heavy as the erythrocytes. The same phenomenon is noted when blood is allowed to clot without agitation; the lighter superficial portion of the clot is then known as the "buffy coat." The rate at which the erythrocytes settle, the so-called *sedimentation rate*, is applied clinically. Why the red cells settle out at different rates in the blood of various pathological conditions is not known. However, the rate is more rapid in tuberculosis, cancer, and acute inflammations. Newborn infants have a very slow rate, whereas normal men have a slower rate than normal women. The rapidity of the rate increases in menstruation and in normal pregnancy.

The erythrocytes are responsible for the opacity of blood. If blood is diluted with water this opacity disappears in a few moments, the fluid becomes translucent, and the blood is said to be hemolyzed or laked. On diluting blood with 0.9 per cent sodium chloride solution, however, no hemolysis occurs. The explanation for this lies in the osmotic behavior of the erythrocytes. Each cell may be considered as a miniature osmometer, the water content of the cell depending upon the osmotic pressure both of the cell contents and of the surrounding medium. If, for example, the cell is in a medium such as 0.9 per cent sodium chloride solution, which has the same osmotic pressure as the cell contents, the water

content of the cell will not change, nor will its size, and the medium is said to be *isotonic* with the cell. If the osmotic pressure of the medium is greater than that of the cell contents, water will be abstracted from the cell, it will decrease in size, and the solution is said to be *hypertonic*. A solution which has a lower osmotic pressure than the cell contents is *hypotonic*; in such a solution, the cell will absorb water and swell, the extent of swelling depending upon the degree of hypotonicity. In a sufficiently hypotonic solution the swollen erythrocyte loses its ability to retain hemoglobin, and hemolysis results. The osmotic pressure at which hemolysis occurs is known clinically as the fragility point, and its determination has a certain diagnostic value.

Other agencies besides osmotic-pressure differences will bring about hemolysis of erythrocytes. These include alkali, ether, chloroform, soaps, bile salts, saponins, certain bacterial toxins, and snake venoms. In these instances hemolysis must be attributed to the actual modification or destruction of the cell stroma.

Human erythrocytes are nonnucleated biconcave disks with an average diameter of about  $8\ \mu$  ( $1\ \mu = 0.001\ \text{mm.}$ ). Mammalian erythrocytes vary in size from species to species, ranging from  $2\ \mu$  to about  $9\ \mu$  in diameter. In the blood of birds, fishes, amphibians, and reptiles the erythrocytes are ordinarily more or less elliptical, biconvex, and nucleated.

The number of erythrocytes present in human blood depends upon many factors, such as age, sex, altitude, exercise, etc. It is usually considered that the blood of a normal adult male contains 5,000,000 erythrocytes per cmm.; for a normal adult female the count is 4,500,000. Increased red-cell count is noted after blood transfusion, during residence at high altitudes, and after strenuous physical exercise; in the latter case a count of 7,040,000 has been observed. An increase is also noted in starvation, after partaking of food, after cold or hot baths, after massage, after partial asphyxia, and after fright, as well as after the administration of certain drugs and accompanying certain diseases, such as cholera, diarrhea, dysentery, and yellow atrophy of the liver. In polycythemia counts as high as 11,000,000 have been noted, and values almost as high have been observed in cyanosis. Experimentally, polycythemia may be produced in animals by the inclusion of cobalt salts in the diet. A decrease in the number of erythrocytes occurs in the different forms of anemia, values as low as 500,000 per cmm. or lower having been noted in pernicious anemia.

Erythrocytes possess the property of grouping together in masses, or "clumping." This action occurs normally on a microscopical scale, and since the cell aggregates settle faster than the discrete cells, clumping is a major factor in determining the sedimentation rate of the blood cells, a characteristic of blood the measurement of which was shown by Fåhræus to have considerable clinical value. If the clumping power of the cells is so enhanced as to produce macroscopically visible clumps, the process is called agglutination. Cells other than erythrocytes (e.g., bacteria) possess this property; when spoken of in connection with the blood the term *hemagglutination* is frequently used. Observation of hemagglutination is the basis for the establishment of blood types, so essential in connection with blood transfusion; indeed, it is agglutination of erythrocytes

which renders incompatible the bloods of donor and recipient. A substance which will bring about hemagglutination is said to contain hemagglutinins; if these are species specific they are known as isohemagglutinins. In human plasma the isohemagglutinins are associated largely with the  $\beta$ - and  $\gamma$ -globulin fractions. Hemagglutinins are abundant in the vegetable kingdom; for a demonstration of hemagglutination, see p. 486.

**Composition of Red Cells.** The red cells contain approximately 65 per cent water and 35 per cent solids. Of the solids, the red chromoprotein hemoglobin comprises about 32 of the 35 per cent; most of the remaining 3 per cent forms the stroma of the red cell, which consists largely of protein, phospholipide, and cholesterol. Inorganic ions in the red cell include potassium, chloride, bicarbonate, and phosphate; of these, potassium is present in largest amount, being comparable quantitatively, and in certain respects equivalent physiologically, to the sodium of the plasma. Organic constituents include various phosphate esters and certain enzymes, such as phosphatases and carbonic anhydrase; this latter is of particular significance in connection with the function of the red cells in the carriage of carbon dioxide by the blood (see Chapter 24). Certain diffusible substances such as glucose and urea are found equally distributed between cells and plasma when concentrations are expressed in terms of the water present; it is important to remember in such comparisons as this that on a percentage basis the amount of water in the cells is much less than that in the plasma.

Although erythrocytes contain oxidative enzymes (the "yellow enzyme" of Warburg was first isolated from horse red cells), the respiratory metabolism of these cells is very small. The major functions of the red cell appear explicable on a purely physicochemical basis in terms of the role of hemoglobin and other substances present in the transport of oxygen and carbon dioxide by the blood.

**Hemoglobin.** Hemoglobin, the red coloring matter of the blood, is the most abundant protein in blood, being usually found to the extent of about 14 to 16 g. per 100 ml. of whole blood. It is normally found entirely within the erythrocytes, from which it may be released by suitable hemolytic agents. It is a readily crystallizable conjugated protein, consisting of a colorless protein portion known as globin, which makes up about 96 per cent of the hemoglobin molecule, and a colored nonprotein portion or prosthetic group which has been shown to be an iron-containing compound belonging to the class of porphyrins. The chemical nature of globin has been discussed in Chapter 6.

The molecular weight of hemoglobin is approximately 67,000, concordant results being obtained by a variety of methods. The iron content of crystalline human hemoglobin is 0.340 per cent. Since this corresponds to a minimal molecular weight of 16,700 on the basis of one Fe atom per molecule, it has been concluded that the hemoglobin molecule contains four Fe atoms, and the physicochemical behavior of hemoglobin is in agreement with this conclusion.

It is now clearly established that several types of human hemoglobin exist. In the prenatal period, the blood contains hemoglobin distinctly different from the adult type. It is called fetal hemoglobin and is recog-

nized by its alkali resistance. Fetal hemoglobin gradually disappears during the first year of life except in certain chronic anemia states in which it continues to be present in the blood. *Sickle-cell anemia*, a disease confined almost exclusively to the Negro, is characterized by an abnormal hemoglobin and a peculiar behavior of the erythrocytes. The cells acquire a crescent shape when subjected to low oxygen tension. Sickle-cell hemoglobin and normal hemoglobin have the same oxygen dissociation curve, similar crystal forms, and identical solubilities, but differ in their electrophoretic mobilities. This difference is sufficient to produce a serious disease which is transmitted by inheritance.

Hemoglobin is readily separated into its protein and prosthetic-group components by treatment with acid, the globin usually being denatured in the process, and the iron-containing portion being obtainable under the proper conditions in the form of an insoluble crystalline compound known as hemin. The formation of hemin crystals is frequently used as a test for blood because of their characteristic appearance and the ease with which they may be obtained. Hemin has been synthesized and its structure is represented by the following formula:

It can be seen that the hemin molecule contains iron in the trivalent form, and that the rest of the molecule consists essentially of four substituted methyl-pyrrole rings linked together by  $\text{—CH=}$  bridges. Such a molecule is known as a metalloporphyrin, the metal in this case being iron. Various isomers of the porphyrin molecule are known, differing in the relative position of the substituting side chains, the isomer found in hemin being called protoporphyrin. To indicate the valence of the iron, which is of importance, it has been suggested that the terms ferroprotoporphyrin and ferriprotoporphyrin be used. Thus hemin is the chloride of ferriprotoporphyrin. The term *heme* is also frequently used as equivalent to ferriprotoporphyrin, hemin then being the chloride of heme. The older term "hematin" has been largely abandoned because of its indefinite connotation; it is roughly equivalent to heme.

When hemin is treated with a suitable reducing agent the ferric iron is reduced to the ferrous state. The resulting ferroprotoporphyrin or reduced heme readily combines with undenatured globin to form a compound which is closely similar to, if not identical with, natural hemoglobin. Thus hemoglobin is a combination of globin with reduced heme,

the iron in the hemoglobin molecule being in the ferrous state. The nature of the combination between the protein and the prosthetic group is not known.

Heme and reduced heme have the ability to combine with other nitrogen-containing compounds besides globin and denatured globin; such substances include other proteins, ammonia, cyanide, nicotine, pyridine, etc. These combinations are known in general as hemochromogens. Spectroscopic and other studies of the various natural and synthetic hemochromogens have thrown much light on our knowledge of the chemical behavior of heme and hemoglobin, and hemochromogen formation has been utilized for the qualitative detection and quantitative determination of hemoglobin. The occurrence of heme in nature as the prosthetic group of the enzymes catalase and peroxidase, and in the cytochromes, has already been discussed (see Chapter 12).

**Combination of Hemoglobin with Oxygen.** A major physiological function of hemoglobin is based upon its ability to react reversibly with oxygen. This reaction may be written as follows:<sup>8</sup>

Under optimal conditions, 1 g. of hemoglobin will combine with 1.36 ml. of oxygen.<sup>9</sup> The product of this reaction, oxyhemoglobin, is as well characterized a compound as hemoglobin, and is quite stable with respect to its oxygen content as long as there is sufficient oxygen present to prevent the reaction from going to the left. Oxyhemoglobin may be crystallized, and a specific form of crystal is obtained from the blood of each individual animal species (see Figs. 107 and 108). Reichert and Brown studied oxyhemoglobin crystals prepared from the blood of more than 100 species of animals from the point of view of their crystallographic characteristics. Species differences are not confined to crystal form only; Barcroft and others have shown that oxyhemoglobin from various sources may differ in spectroscopic characteristics and in affinity for oxygen. Since hemin crystals are identical no matter from what species the blood is obtained, the species differences in oxyhemoglobins must presumably be related to differences in the globin portion of the molecule.

The reversibility of the reaction between hemoglobin and oxygen to form oxyhemoglobin implies that the relative amounts of hemoglobin and oxyhemoglobin present in blood will depend upon the concentration of oxygen present, which in turn is proportional to the oxygen tension (Henry's Law). The oxygen tension within the red cells is determined

<sup>8</sup> The reaction is written in the form given for purposes of simplicity. It has already been pointed out that there are four Fe atoms per molecule of hemoglobin, and it is known that hemoglobin combines with oxygen in the proportion of one O<sub>2</sub> molecule per atom of Fe. Thus the reaction should really be written:  $\text{Hb}_4 + 4\text{O}_2 \rightleftharpoons \text{Hb}_4\text{O}_8$ . Furthermore, this latter reaction provides for the possibility of intermediate compounds such as  $\text{Hb}_4\text{O}_2$ ,  $\text{Hb}_4\text{O}_4$ , and  $\text{Hb}_4\text{O}_6$ , the formation of which would depend on the amount of oxygen available; and Pauling and others have shown that the sigmoid curve relating oxyhemoglobin formation to oxygen tension is explicable on the basis of equilibria involving the formation of such intermediate stages in oxygenation.

<sup>9</sup> Bernhart and Skeggs: *J. Biol. Chem.*, **147**, 19 (1943).

largely by the oxygen tension of the plasma, since oxygen is freely diffusible across the red-cell membrane.

The relation between the degree of oxygenation of hemoglobin and the oxygen tension is usually expressed graphically in the form of a

FIG. 107. OXYHEMOGLOBIN CRYSTALS FROM BLOOD OF THE RAT.

FIG. 108. OXYHEMOGLOBIN CRYSTALS, FROM BLOOD OF THE DOG.

These illustrations were reproduced from photomicrographs furnished by the late Prof. E. T. Reichert of the University of Pennsylvania.

Courtesy, Van Slyke and Peters: *Quantitative Clinical Chemistry*.

curve, the *oxygen dissociation curve*, which is illustrated by Fig. 109. The effect of such variables as pH and temperature on the ability of hemoglobin to combine with oxygen may be studied by noting their influence on the shape of the oxygen dissociation curve. From the curve it can be seen that when blood is in equilibrium with ordinary room air

(oxygen tension = *ca.* 150 mm.Hg) or with the alveolar air of the lungs (oxygen tension = *ca.* 90 to 100 mm.Hg), practically all of the hemoglobin is oxygenated, i.e., the per cent saturation of the blood with oxygen is from 95 to 100 per cent. As the blood courses through the tissue capillaries, however, where there is a constant demand for oxygen, oxygen diffuses out of the plasma into the tissue fluids and the plasma oxygen

FIG. 110. RELATION BETWEEN WAVELENGTH AND LIGHT ABSORPTION FOR HEMOGLOBIN AND OTHER BLOOD PIGMENTS, ALL AT A CONCENTRATION OF 1 G. PER LITER AND AT A SOLUTION DEPTH OF 1 CM.

tension falls to about 40 mm.Hg. At this tension the oxyhemoglobin has yielded up about one-quarter of its combined oxygen by dissociation; thus normal venous blood contains about 75 per cent oxyhemoglobin and 25 per cent hemoglobin, or is 75 per cent saturated with oxygen. Further lowering of the oxygen tension leads to increased dissociation of oxyhemoglobin; in the extreme condition of cyanosis only a minor portion of the pigment may be oxygenated. The sigmoid shape of the curve is considered to have some physiological significance. As the oxygen tension is lowered (i.e., as the demand for oxygen becomes greater), a given de-

crease in tension produces a greater dissociation of oxyhemoglobin than is produced for the same decrease in tension at high tensions.

The physiological function of hemoglobin is not confined to oxygen transport; it is of equal significance in the carriage of carbon dioxide by the blood. This function is discussed in detail in Chapter 24.

**Other Reactions of Hemoglobin.** In addition to its ability to react with oxygen, hemoglobin will react with a variety of other compounds, such as carbon monoxide, nitric oxide, hydrogen sulfide, ferricyanide, etc., the product in most cases being a colored compound which, like hemoglobin and oxyhemoglobin, may usually be identified by its characteristic absorption spectrum.

FIG. 111. CARBON MONOXIDE HEMOGLOBIN CRYSTALS FROM OX BLOOD.

Courtesy, Boor: *J. Gen. Physiol.*, **13**, 307 (1930).

The absorption spectra of hemoglobin and some hemoglobin derivatives are shown in Fig. 110 as they are obtained quantitatively with the spectrophotometer. The actual extent to which the light is absorbed is indicated by the data in Fig. 110.

The combination between hemoglobin and carbon monoxide to form carbon monoxide hemoglobin is of interest because of the constant presence of small amounts of carbon monoxide in city air. Carbon monoxide hemoglobin is a bright red pigment which may be crystallized (see Fig. 111). Carbon monoxide has about 200 times the

affinity for hemoglobin that oxygen has; furthermore, the formation of carbon monoxide hemoglobin prevents hemoglobin from combining with oxygen, presumably because both gases compete for the same spot in the hemoglobin molecule. Carbon monoxide will in fact displace oxygen from oxyhemoglobin, as this reaction indicates:

This reaction ordinarily proceeds from left to right; it is however reversible if the concentration of oxygen is made high enough, and in this fact lies the therapy for carbon monoxide poisoning. Carbon monoxide hemoglobin is not toxic in itself; death from carbon monoxide poisoning is presumably due to failure of sufficient oxygen to reach the tissues because of the decreased oxygen-carrying capacity of the blood when a significant proportion (40 to 60 per cent or more) of the total hemoglobin is in the form of carbon monoxide hemoglobin. The anoxia of carbon monoxide poisoning is not due entirely to passive blocking of oxygen transport by hemoglobin; the oxyhemoglobin present in blood containing much carbon monoxide hemoglobin has been shown to be less efficient in releasing oxygen to the tissues under a given gradient of oxygen tension. The blood of city dwellers regularly contains over 1 per cent of the total

hemoglobin as carbon monoxide hemoglobin; tobacco-smoking may increase this to 5 per cent.

When hemoglobin is treated with certain oxidizing agents, either *in vitro* or *in vivo*, the substance methemoglobin is formed. This is a brown pigment which differs from hemoglobin and oxyhemoglobin in that the iron is in the *ferric* form, i.e., methemoglobin is a combination of heme, or ferriprotoporphyrin, and globin. Methemoglobin is usually detected by means of its characteristic absorption spectrum (see Fig. 110). It does not combine with either oxygen or carbon monoxide, but does form a colored cyanide derivative. There is little or no methemoglobin in normal blood; the appearance of a methemoglobinemia is noticed in certain diseases and after the administration of certain drugs, among them sulfanilamide. Methemoglobin is not toxic; its presence in blood simply means a proportional reduction in the oxygen-carrying capacity of the blood. The clinical induction of a moderately severe methemoglobinemia has been proposed as an aid in the treatment of cyanide poisoning, since methemoglobin combines with cyanide and may thus prevent the latter from reacting with enzymes in the tissues.

**Origin of Hemoglobin.** Hemoglobin is synthesized in the body from the ingredients of the diet; iron, a source of the porphyrin nucleus, and amino acid precursors of the protein globin are of obvious importance in this connection. It is known that inorganic iron of the diet cannot be converted into hemoglobin without the presence of catalytic traces of copper; the way in which copper functions is not known.<sup>10</sup> Studies on the origin of the porphyrin nucleus and on the significance of dietary amino acids in hemoglobin synthesis have yielded little definite information; work with isotopes indicates that glycine and acetic acid may be precursors of the porphyrin ring (see also Chapter 33). In the adult animal the erythrocytes are formed in the bone marrow; in the embryo the liver is an important source of red-cell production, and the possibility that in the adult the liver retains a vital part in hemoglobin synthesis and erythrocyte formation cannot be overlooked. In the nutritional anemias there is usually a dietary deficiency leading to impaired hemoglobin formation; when the deficiency is corrected the anemia disappears. In pernicious anemia there appears to be lacking a factor which is necessary for the production of mature erythrocytes. This factor, vitamin B<sub>12</sub> or cyanocobalamin (see p. 1207), has been isolated and found to contain 4.5 per cent of cobalt. Interestingly, both vitamin B<sub>12</sub> and folic acid correct the maturation defect in pernicious anemia, but folic acid fails to prevent the neurological complications which commonly occur. It is believed that the absorption of vitamin B<sub>12</sub> is defective in pernicious anemia and that this is due to the lack of a factor secreted by the stomach which is known as the *intrinsic factor of Castle*. This would explain why vitamin B<sub>12</sub> is exceedingly effective when given parenterally even in minute doses, but relatively ineffective when administered orally.

**The White Cells.** The white corpuscles (or leukocytes) of human blood differ structurally from the red corpuscles (or erythrocytes) in many

<sup>10</sup> Glass: *Copper Metabolism*, Baltimore, Johns Hopkins University Press, 1950; Marston: *Physiol. Revs.*, 32, 66 (1952).

particulars, such as being larger in size, containing at least a single nucleus, and possessing ameboid movement. They are typical animal cells and therefore contain the following substances which are customarily present in such cells: Proteins, fats, glycogen, purines, enzymes, phosphatides, cholesterol, inorganic salts, and water. Compound proteins make up the chief part of the protein quota of leukocytes, the nucleoproteins predominating. Powerful proteolytic and glycolytic enzymes are also present. It is believed that there are two proteolytic enzymes in leukocytes, one active in alkaline solution and present in the polynuclear cells, and the other active in acid medium and present in mononuclear cells. It is claimed that the granular leukocytes originate in the bone marrow, whereas the nongranular leukocytes (lymphocytes) have a lymphatic origin (lymph glands or lymphoid tissue); this matter of origin is uncertain. The normal number of leukocytes in human blood varies between 5,000 and 10,000 per cmm. The ratio between the leukocytes and erythrocytes is about 1:350 to 500.

A leukocytosis is said to exist when the number of leukocytes is increased for any reason. Leukocytoses may be divided into two general classes: the physiological and the pathological. Under the physiological form would be classed those leukocytoses accompanying pregnancy, parturition, digestion, and excessive physical exercise, as well as those due to mechanical and thermal influences. Leukocytosis is also associated with such emotional states as fear, rage, or apprehension. The leukocytoses spoken of as pathological are the inflammatory, infectious, post-hemorrhagic, toxic, and experimental forms, as well as the type which accompanies malignant disease.

**Chylomicrons.** Blood contains myriads of spherical particles, about 0.5 to 1.0 micron in diameter, which are highly refractive and show Brownian movement. These were first recognized by Boyle in 1665, but were later described more fully by Müller who called them hemaconia or blood dust. However, Gage showed them to be minute fat globules, and curves of the chylomicron counts following the ingestion of fat have been studied in digestion experiments.

It has long been known that hyperlipemia is common in diabetes and that the incidence of atherosclerosis is high in this disease. The relationship of steroids in the blood to arterial degeneration has aroused intense interest.<sup>11</sup> Evidence is accumulating which suggests that steroid macromolecules may have an important causative role in atherosclerosis. The original finding of Hahn<sup>12</sup> (which has been repeatedly confirmed) that heparin has a striking effect on reducing postprandial hyperlipemia may perhaps be of both theoretical and clinical significance.

**Blood Coagulation.** When blood is withdrawn from a vein and put into a test tube, it will clot solidly in less than 10 minutes. After about 30 minutes the coagulum begins to retract, with the expression of a clear serum. These seemingly simple phenomena are the result of a complex series of reactions. The actual clot is due to the conversion of a soluble protein, fibrinogen, to fibrin, which separates as fibrils forming a mesh-

<sup>11</sup> Gofman, Jones, Lindgren, Lyon, Elliott, and Strisower: *Circulation*, **2**, 161 (1950).

<sup>12</sup> Hahn: *Science*, **98**, 19 (1943).

work that incloses both the cellular and plasma elements of the blood. Fibrinogen is changed to fibrin by the action of the enzyme thrombin. For the formation of this clotting factor, at least five agents have been shown to be essential: prothrombin, labile factor, calcium, thromboplastinogen, and platelets.

**PROTHROMBIN.** Of the five basic thrombinogenic factors, prothrombin is the most clearly characterized and differentiated as a functional entity. It is a protein containing about 4 per cent carbohydrate. Its proenzyme nature is indicated by the fact that it becomes inactivated at 58 to 60° C. It is quantitatively removed from oxalated plasma by adsorbents such as tricalcium phosphate and barium sulfate and may be completely recovered from these adsorbents by elution with sodium citrate.

Vitamin K is essential for the synthesis of prothrombin, but the amount needed is exceedingly small. An adult dog requires only about 0.5  $\mu$ g. of natural vitamin K per kg. of body weight daily to maintain a normal level of prothrombin. It is likely that the human requirements are about the same. The action of vitamin K can be satisfactorily explained by postulating that it functions as a prosthetic group combining with an *apoenzyme* ( $\mathcal{A}$ ) to form the *holoenzyme* ( $\mathcal{A}$  K), and that it is this enzyme which produces prothrombin. A deficiency of either apoenzyme or vitamin K results in a diminution of the holoenzyme and therefore in a decrease of the body's capacity to produce prothrombin. In the newborn a deficiency of vitamin K can easily occur due to inadequate intake. In the adult faulty absorption of vitamin K from the intestines is the most common cause for deficiency. Vitamin K<sub>1</sub>, which is fat-soluble, requires bile salts for its absorption. Any condition therefore, such as biliary obstruction, in which bile does not enter the intestinal tract will bring about an inadequate absorption of vitamin K.

While the concept of an apoenzyme is still largely an hypothesis, the hypoprothrombinemia observed in certain liver diseases which is refractory to vitamin K is satisfactorily explained by the assumption that the apoenzyme is diminished. Likewise, congenital hypoprothrombinemia, which is unaffected by vitamin K, can be attributed to a lack of the factor which with vitamin K forms the enzyme that produces prothrombin.

Hypoprothrombinemia can be produced by a number of compounds which act as anti-vitamin-K agents. The best known of these is dicoumarol [3,3'-methylenebis(4-hydroxycoumarin)] which Link isolated from spoiled sweet-clover hay. It may be postulated that dicoumarol depresses the production of prothrombin by replacing vitamin K in the enzyme system

Æ K according to the equation:  $\text{Æ K} + \text{D} \rightleftharpoons \text{Æ D} + \text{K}$ , where D stands for dicoumarol. The reaction is reversible and therefore the inhibitory action of dicoumarol can be counteracted by administering vitamin K. Dicoumarol and several other vitamin K antagonists are employed therapeutically to produce hypoprothrombinemia as a means of lessening the tendency to thrombosis.

Prothrombin is readily and accurately determined by means of the prothrombin time. In this procedure an excess of a standardized tissue extract such as acetone-dehydrated rabbit brain is added to recalcified plasma, and the clotting time is determined. By means of a curve, the prothrombin time can be expressed as per cent of normal clotting time. Under the conditions of the test, the clotting or prothrombin time is a direct measure of the prothrombin concentration. A second method known as the two-stage procedure consists in diluting plasma, after it has been defibrinated with a minute amount of thrombin, and converting all the prothrombin to thrombin by adding thromboplastin and calcium. The thrombin is determined by the speed with which it coagulates a fixed amount of fibrinogen.

Research indicates that only part of the prothrombin in human blood is in the active form; the remainder is present in a precursor state to which the name prothrombinogen has been given. In the blood of the newborn baby, prothrombinogen is lacking, but the concentration of active prothrombin is the same as in adult blood.<sup>13</sup> The prothrombin time, which measures only free or active prothrombin and is uninfluenced by prothrombinogen, is therefore normal. Since the two-stage method does not distinguish between free and inactive prothrombin but determines only total prothrombin, the concentration as determined by this method is only about one-third of the adult level. Since the newborn baby with a normal prothrombin time has no bleeding tendency, irrespective of the low prothrombin shown by the two-stage method, it may be concluded that only active prothrombin participates in hemostasis, and that therefore the prothrombin time is the more reliable test.

**LABILE FACTOR.** When human oxalated plasma is stored at 4° C., the prothrombin time becomes progressively prolonged. Since the addition of fresh plasma deprothrombinized by adsorption with  $\text{Ca}_3(\text{PO}_4)_2$  restores the prothrombin time of stored plasma to normal, it must be concluded that the disappearance of a factor other than prothrombin must account for the loss of prothrombin activity during storage. This agent has been named *labile factor*, but is also known as *Factor V* or *Ac-globulin* (Ac = accelerator). Like prothrombin, it is a protein and is inactivated at 58 to 60° C. Unlike prothrombin it is not adsorbed by  $\text{Ca}_3(\text{PO}_4)_2$  nor is its concentration in the blood diminished by vitamin K deficiency or by dicoumarol. The concentration of labile factor is relatively low in human blood as compared with rabbit blood, which contains 50 times more; yet a significant diminution of this agent rarely occurs clinically.

**CALCIUM.** Like prothrombin and labile factor, calcium reacts stoichiometrically in the formation of thrombin. The minimal requirement for

---

<sup>13</sup> Quick, Murat, Hussey, and Burgess: *Surg. Gynecol. and Obst.*, **95**, 671 (1952).

optimum clotting of human plasma is 0.0012 M. Since the level of calcium in the blood at which fatal tetany occurs is still entirely adequate for normal clotting, hypocalcemia as a cause of bleeding is highly improbable.

Prothrombin, labile factor, and calcium may for convenience be considered to constitute the prothrombin complex. The interrelation of these factors is stoichiometric, and since labile factor and calcium are normally in excess, prothrombin is the limiting factor and therefore the determinant of the prothrombin time except in very rare pathological states.

**THROMBOPLASTINOGEN.** Plasma contains a protein, closely associated in physical properties with fibrinogen and globulin, which reacts with a platelet factor to form thromboplastin. This agent, which has been named *thromboplastinogen*, is deficient in hemophilia. It is probable therefore that it is the same or closely related to the substance which some investigators call *antihemophilic globulin*.

Curiously, no preformed thromboplastin is found in the blood. Nevertheless, nearly all other tissues of the body contain this agent, and in some organs such as the lungs, brain, and placenta, it is present in relatively high concentration.

**PLATELETS.** These cells contain a factor which reacts with thromboplastinogen to form thromboplastin. The clotting agent occurs in the portion of the platelet called the granulomere. It is heat-stable and is probably a lipide with a high molecular weight. In addition to the participation of platelets in the formation of thrombin, they play an important role in clot retraction. Intact platelets adhere to the shafts of fibrin and, probably as the result of morphological alterations, cause a twisting, shortening, and bending of fibrin strands that results in a condensation of the fibrin mass. Platelets have a third function in hemostasis. Lysis of these cells is accompanied by the appearance in the serum of a vasoconstrictor called *serotonin* or *thrombotonin*, which is chemically 5-hydroxytryptamine. It is probable that this compound exercises an important function in stopping the flow of blood in hemorrhage.

**THE CLOTTING REACTION.** The basic reason why circulating blood remains fluid is that it contains no active thromboplastin. For this substance to form, platelets must interact with thromboplastinogen, but before even this can occur, thromboplastinogen must be activated by means of thrombin. The probable sequence of reactions is:

- (1) thromboplastinogen  $\xrightarrow{\text{thrombin}}$  thromboplastinogen A (activated)
- (2) thromboplastinogen A + platelet factor = thromboplastin
- (3) thromboplastin + labile factor + calcium + prothrombin =  
thrombin
- (4) fibrinogen  $\xrightarrow{\text{thrombin}}$  fibrin

Thrombin has a dual function: it clots fibrinogen and it activates thromboplastinogen. Through the latter it initiates a chain reaction, for as it activates thromboplastinogen, more thrombin is formed, accelerating the cycle of reactions. A break or injury of the vessel wall may liberate enough tissue thromboplastin to produce the initial thrombin that starts

the clotting reaction. The prompt removal of thrombin is therefore necessary to safeguard against uncontrolled and massive intravascular clotting. Experimental evidence has been obtained indicating that the physiological antithrombin is fibrin.

Owing to the ability of fibrin to adsorb thrombin with avidity and because of the tremendous surface it presents to the serum dispersed in the reticulum of the clot, the removal of thrombin by fibrin is exceedingly efficient and the chain reaction is effectively held in abeyance. Since the intimate contact between serum and fibrin surface is lost when clot retraction occurs, it is very likely that this process may play a significant role in intravascular clotting.

There is increasing evidence that the clotting reactions in addition to their function in hemostasis may perhaps participate in immunological and other defense mechanisms. It is probably not accidental that thromboplastin is widely distributed in various tissues and that the daily turnover of prothrombin is nearly equal to the amount in circulation. As the physiological significance of blood clotting becomes better understood, a number of factors directly or indirectly associated with these reactions may be better evaluated. Among such factors is the antithrombin of the serum. This agent, which occurs in the albumin fraction, neutralizes large quantities of thrombin, but its action is so slow that it does not interfere with the conversion of fibrinogen to fibrin and therefore has no true anticoagulant action.

*Fibrinolysin* is an enzyme which dissolves fibrin. It is present in the blood as a zymogen, profibrinolysin. Interestingly, certain bacteria produce products which can activate profibrinolysin. Such activators are streptokinase and staphylokinase.

Another factor which markedly influences the clotting of blood is *heparin*, a mucopolysaccharide containing mucoitin-sulfuric acid. Heparin is present in the mast cells of Ehrlich as polychromatic-staining granules. The amount occurring in the blood is extremely small, but in anaphylactic shock its concentration may become sufficiently high to make the blood incoagulable. Heparin itself has little anticoagulant action, but it forms a powerful antithrombin with a cofactor which is present in the albumin fraction of serum.

**Medicolegal Tests for Blood.** The analysis of a specimen for the presence of blood may be of utmost significance. Often it is even more important to determine whether the blood is of human origin. To establish the presence of blood, a portion of the material under investigation should be extracted with 0.9 per cent sodium chloride solution and examined under the microscope. If the material contains relatively fresh blood, erythrocytes may be found and identified. An aqueous extract should be examined spectroscopically or, better, extracted with acid alcohol and examined with the spectroscope for absorption bands of acid hematin. The preparation and identification of hemin crystals is a satisfactory way to detect blood. Even old blood will readily yield these dark-brown or chocolate crystals, provided the specimen has not been exposed to a high temperature or to direct sunlight for a long period. If the amount of blood is very small, detection by the guaiac test or the benzidine reaction

is of great practical usefulness. These tests are exceedingly delicate and reliable, but it is essential that the reagents be properly prepared and tested on control solutions of highly diluted blood.

After the presence of blood is established by these tests, the final step is its identification as to species origin. This can be done only by immunological procedures of which the precipitin test is the most satisfactory. This test is founded on the observation that when serum of one animal is injected into an animal of a different species, the latter will develop in its serum an agent which will react with the proteins of the foreign serum and cause the formation of a precipitate. The precipitin test is highly delicate. It will detect blood in high dilution. It is likewise very specific, since overlapping occurs only in very closely related species.

**Lymph.** Lymph may be considered the middleman in the transactions between blood and tissues. It is the medium by which the nutritive material and oxygen transported by the blood for the tissues are brought into intimate contact with those tissues and thus utilized. In the further fulfillment of its function, the lymph bears from the tissues water, salts, and the products of the activity and catabolism of the tissues, and passes these into the blood. Lymph therefore exercises the function of a go-between for blood and tissues. It bathes every active tissue of the animal body, and is believed to have its origin partly in the blood and partly in the tissues.

In chemical characteristics, lymph resembles blood plasma. In fact, it has been termed "blood without its red corpuscles." Lymph from the thoracic duct of a fasting animal or from a large lymphatic vessel of a well-nourished animal is of a variable color (colorless, yellowish, or slightly reddish) and alkaline in reaction to litmus. It contains fibrinogen, prothrombin, and leukocytes, and coagulates slowly, the clot being less firm and bulky than the blood clot. Serum albumin and serum globulin are both present in lymph, the albumin predominating in a ratio of about 3 or 4:1. The principal inorganic salts are sodium salts (chloride and bicarbonate); the phosphates of potassium, calcium, magnesium, and iron are present in smaller amount.

Substances which stimulate the flow of lymph are termed lymphagogues. Such substances as sugar, urea, certain salts (especially sodium chloride), peptone, egg albumin, extracts of dog's liver and intestine, crab muscles, and blood leeches are included in this class.

In a fasting animal, the lymph coming from the intestine is a clear, transparent fluid possessing the characteristics already outlined. After a meal containing fat has been ingested, this intestinal lymph is white or milky. This is termed *chyle*, and is essentially lymph possessing an abnormally high (5 to 15 per cent) content of emulsified fat. This chyle is absorbed by the lacteals of the intestine and transported to the lower portion of the thoracic duct. Apart from the fat content, the composition of lymph and chyle are similar.

**Cerebrospinal Fluid.** On tapping the spinal canal a water-clear fluid is obtained which is essentially a plasma filtrate formed by the choroid plexus. This fluid fills the two lateral and the third and fourth ventricles, the subarachnoid, and the spinal canal. Spinal fluid usually contains less

than 50 mg. of protein per 100 ml., of which 80 per cent is albumin, the remainder globulin.

The osmotic pressure and the pH of the spinal fluid are the same as that of the plasma, whereas the glucose and calcium contents are roughly 50 per cent as great. The sodium chloride concentration is distinctly higher than that of plasma, while the bicarbonate concentration is about the same.

The analysis of the cerebrospinal fluid supplies valuable diagnostic information in the study of diseases involving the central nervous system. In general, the quantitative methods developed for plasma can be applied with minor modifications in the study of spinal fluid.

The *colloidal gold test* of Lange may also be used. In this test a colloidal gold solution is mixed with progressively increasing dilutions of cerebrospinal fluid. The orange-red color of Lange's solution is changed when cerebrospinal fluid from certain pathological conditions is tested.

## EXPERIMENTS ON BLOOD

### IDENTIFICATION OF BLOOD

**1. Microscopical Examination.** Place a drop of diluted blood on a microscopical slide and cover with a coverglass. Examine under a microscope.

**2. Tests for Various Constituents.** To 50 ml. of water in a large casserole, add 2 drops of acetic acid and bring to a boil. At the point of vigorous boiling, add 10 ml. of defibrinated blood slowly from a pipet, with stirring. Continue boiling and stirring for one minute after all the blood has been added. Then pour the mixture immediately onto a large folded filter which has been prepared beforehand. If the filtrate is not practically clear and colorless it should be discarded and the process repeated with more blood. Reserve the coagulum for further use. Why is the coagulum colored dark brown? Evaporate the filtrate to about 25 ml., filtering off any precipitate which may form in the process. Make the following tests upon the filtrate:

(a) **BENEDICT'S TEST.** To 5 ml. of Benedict's solution add 5 drops of neutralized filtrate and boil one minute. Explain.

(b) **CHLORIDES.** To a small amount of the filtrate in a test tube add a few drops of nitric acid and a little silver nitrate. In the presence of chloride, a white precipitate of silver chloride will form.

(c) **PHOSPHATES.** Test for phosphates by nitric acid and molybdate solution according to directions given on p. 213.

(d) **CALCIUM.** To 5 ml. of filtrate add 0.1 ml. of 4 per cent ammonium oxalate. Calcium oxalate precipitates as fine crystals. For crystalline form see p. 855.

(e) **TEST FOR IRON.** Incinerate a small portion of the coagulum obtained above, in a porcelain crucible. Cool, dissolve the residue in dilute hydrochloric acid, and test for iron by potassium ferrocyanide or ammonium thiocyanate. Which of the constituents of the blood contains the iron?

(f) **CRYSTALLIZATION OF SODIUM CHLORIDE.** Place the remainder of the filtrate in a watch glass and evaporate it on a water bath. Examine the crystals under the microscope and compare them with those in Fig. 112.

**3. Hemin Tests.** Hemoglobin is readily split into its globin and hemin components by means of heat and acetic acid. Hemin forms characteristic crystals which are readily recognized under the microscope and serve as a reliable test for blood.

(a) **TEICHMANN'S METHOD.** Place a very small drop of blood on a microscopical slide, add a small drop of water, and stir to lake the blood. Add a fraction of a drop of dilute (0.9 per cent) sodium chloride or potassium chloride solution and carefully evaporate to dryness over a low flame. Put a coverglass in place, run underneath it a drop of glacial acetic acid, and warm gently until the formation of gas bubbles is noted. Add another drop of glacial acetic acid, cool the preparation, examine under the microscope, and compare the crystals with those shown in Fig. 113.

(b) **NIPPE'S METHOD.** Spread a small drop of blood on a slide in the form of a film and evaporate to dryness over a low flame. Now add 2 drops of a solution containing 0.1 g. each of potassium chloride, iodide, and bromide in 100 ml. of glacial acetic acid. Place a coverglass in position and heat gently over a low flame until gas bubbles form and the solution boils. Run 1 to 2 drops of the reagent underneath the coverglass and examine under a microscope. Compare the crystals with those shown in Fig. 113.

FIG. 112. SODIUM CHLORIDE.

FIG. 113. HEMIN CRYSTALS FROM SHEEP BLOOD.

Reproduced from a photomicrograph furnished by the late Prof. E. T. Reichert, of the University of Pennsylvania.

This method is more rapid than Teichmann's method and crystals of inorganic chlorides are not formed. In Teichmann's method crystals of sodium chloride (Fig. 112) often obscure the hemin crystals. For the preparation and purification of hemin on a large scale, see *Organic Syntheses*, 21, 53, New York, John Wiley & Sons, Inc., 1941.

**4. Guaiac Test.** This method is sensitive and valuable for detecting blood. Care must be taken not to use too concentrated a solution of guaiac since a voluminous precipitation of resinous material may easily obscure the blue color. Substances other than blood, such as milk, pus, and saliva, may give a positive test, but after boiling for 15 to 20 seconds they no longer yield a blue color with guaiac, whereas blood similarly subjected to boiling still yields a positive test.

The test follows: By means of a pipet drop a solution of guaiac in glacial acetic acid (strength about 1:60) into the solution under examination<sup>14</sup> until a turbidity is observed, and add hydrogen peroxide, drop by drop, until a blue color is obtained.

**5. Benzidine Reaction.** This test is one of the most delicate for detecting blood, but care must be taken to use a good grade of benzidine, since the sensitivity is greatly influenced by the purity of the reagent. The test depends on the action of hemoglobin, which catalytically decomposes hydrogen peroxide, thereby liberating oxygen which oxidizes benzidine to a blue or green derivative. Since an excess of hydrogen peroxide interferes with the reaction, it is essential that the details of the procedure be followed scrupulously. It is particularly important that the peroxide be added last. The benzidine solution is unstable, especially when exposed to light. It should therefore be prepared fresh daily and kept in a brown bottle or a dark place. The test is particularly valuable to detect occult blood in the feces.<sup>15</sup>

The test is performed as follows: To 3 ml. of a saturated solution of benzidine in glacial acetic acid<sup>16</sup> add 2 ml. of the solution to be tested and 1 ml. of 3 per cent hydrogen peroxide. A positive test is indicated by a blue or green color. The following modification is a much more delicate and reliable test.

**Confirmatory Test.** Make 10 ml. of the solution acid with acetic acid and extract by shaking with 5 ml. of ether. The acid breaks up the hemoglobin to globin and heme and the latter is extracted by the ether. Pour off the ether into a small evaporating dish. Put on a hot water bath (with the flame turned out). Evaporate to dryness. To the residue add a few drops of water, a drop of saturated solution of benzidine in glacial acetic acid, and a drop of 3 per cent hydrogen peroxide. A blue or green color indicates blood.

**Lyle, Curtman, and Marshal Modification.** Into a perfectly clean dry test tube introduce 1.4 ml. of benzidine solution,<sup>17</sup> add 0.2 ml. of water or glacial acetic acid, then 1 ml. of the fluid to be tested and finally 0.4 ml. of 3 per cent hydrogen peroxide. Note the appearance of a blue color, which reaches its maximum in 5 to 6 minutes.

**6. Hemochromogen Test.** Add 2 or 3 drops of Takayama's solution<sup>18</sup> to a small piece of suspected material on a slide. Cover with a coverglass. Examine

---

<sup>14</sup> Alkaline solutions should be made slightly acid with acetic acid, since the blue end reaction is very sensitive to alkali. This is particularly necessary if an alcoholic solution of guaiac is used.

<sup>15</sup> Hughes: *Brit. Med. J.*, 2, 970 (1952).

<sup>16</sup> Glacial acetic acid is preferable, but if it is not available, alcohol acidified with acetic acid may be used.

<sup>17</sup> Benzidine solution may be prepared as follows: Place 4.33 ml. of glacial acetic acid in a small Erlenmeyer flask, warm to 50°, and add 0.5 g. of benzidine. Heat the flask for eight to ten minutes in water at 50°. To the resultant solution add 19 ml. of distilled water. This solution may be kept for several days without deterioration.

<sup>18</sup> A mixture of 3 ml. of 10 per cent NaOH, 3 ml. of pyridine, 3 ml. of a saturated solution of glucose, and 7 ml. of water. The solution works rapidly in the cold if at least 24 hours old. With a fresh solution, warming or more time is necessary. It keeps for from one to two months.

under the microscope. Salmon pink crystals should appear in 1 to 6 minutes. At the same time the color changes through green-brown and dark red to pink, indicating the formation of a hemochromogen and confirming the test. The crystals have a shallow rhomboid form (see Fig. 114).

This method is simpler to use than the hemin test and may be used to confirm the latter in doubtful cases. It is not always given by old blood stains (over six months old) and hence does not replace the hemin test. The glucose may act as a reducing agent as well as by decreasing the solubility of the

FIG. 114. HEMOCHROMOGEN CRYSTALS.

Prepared and photographed by Dr. Arthur G. Cole,  
University of Illinois, College of Medicine.

hemochromogen. Schumm has cast some doubt on the specificity of this test for blood.

**7. Immunological Determination of Blood Species.** The serum proteins give immunological reactions, such as the precipitin reaction, which are specific not only for the individual proteins of the serum but also for the species of animal from which the serum is obtained. These immunological reactions are therefore used in medico-legal investigations to determine the species to which a particular blood sample or stain belongs. The species specificity of these reactions is demonstrated in the following experiments on the precipitin reactions of dog, beef, and human serums. Antiserums against human blood react with the serums of some of the higher apes, indicating a close relationship between the various species. Usually, however, even these reactions show quantitative differences which are sufficient to differentiate between human and other bloods.

(a) **PREPARATION OF IMMUNE SERUMS (ANTISERUMS).** Prepare approximately 1 per cent solutions of dog, beef, and human serum proteins by diluting 15 ml. of the clear serums to 100 ml. with physiological (0.9 per cent) salt solution. Immunize rabbits against each of these solutions (antigens) by injection of the diluted serums into the marginal ear vein. Make the first injection with 1 ml. of antigen and follow with injections of 2, 4, 6, and 8 ml. portions at intervals of three or four days. On the fourth day after the last injection, collect 1 ml. of blood and test the serum for precipitin content by the method

described below. If the precipitin is present in sufficiently high titer, bleed the rabbit from the heart, allowing the blood to coagulate. Transfer the clear serum to sterile vials closed with rubber stoppers. Add a few drops of chloroform to each vial as a preservative, and keep vials in a refrigerator when not in use.

*An alternative method for preparing the antiserums is as follows:* Twenty-five ml. of serum is diluted with 80 ml. of distilled water, and to this solution 90 ml. of 10 per cent potassium alum is added. The pH is adjusted to the isoelectric point specific to the alum-protein complex (human serum, pH 6.5) with 5 N NaOH. The precipitate is washed twice with 200 ml. saline containing 1:10,000 merthiolate, and then is suspended in 100 ml. of saline (1:10,000 merthiolate).

The immunizing dose is 10 ml. of the suspension, which is injected intramuscularly—5 ml. into each hind leg of a rabbit. After 15 to 20 days the rabbit is taken off food for 24 hours and then bled. The serum obtained is tested for specificity and sensitivity. For a positive result a precipitin at a dilution of a 1:100 antigen should be obtained within five minutes. As a control, an antigen of a species to which the rabbit is not sensitized should show no precipitin in a dilution of 1:50.

(b) TITRATION OF ANTISERUMS. Prepare the following dilutions of the antigen (diluted serum or protein solution to be tested) using physiological saline as diluent: 1:100; 1:1,000; 1:10,000; 1:50,000. Transfer 1 ml. of each dilution to a separate small test tube which must be scrupulously clean and dry. With a capillary pipet carefully introduce 0.2 ml. of the immune serum at the bottom of each tube so as to stratify the antigen solution above the serum. With a 1:1,000 dilution, a white ring or cloud will form at the interface in a few minutes if the test is positive.

For control, place in one test tube 1 ml. of a 1:50 dilution of an antigen against which the rabbit was not immunized, and add 0.1 ml. of the antiserum as in the test above. For a second control, transfer 1 ml. of the 1:1,000 dilution of the antigen to a test tube and add 0.1 ml. of normal rabbit serum. No precipitation should form in either tube.

(c) IMMUNOLOGICAL EXAMINATION OF BLOOD STAINS. Extract the stain with 1 or 2 ml. of physiological salt solution. Filter and use the filtrate for making up dilutions of antigen and for precipitin reactions, as described above.

**8. Hemagglutination.** The common garden bean, such as the scarlet runner,<sup>19</sup> contains a protein substance which exhibits the interesting property of causing clumping or agglutination of red blood corpuscles.

Dilute defibrinated blood<sup>20</sup> ten times with physiological sodium chloride solution (0.9 per cent) and place 1 ml. in each of three small test tubes.

Grind 3 beans to a fine meal in a coffee mill or with mortar and pestle and extract for a few minutes with 0.9 per cent sodium chloride solution. Filter and add 0.05 ml. (about 2 to 3 drops) of the filtered extract to the first of the blood tubes, 0.01 ml. to the second, and 0.05 ml. of 0.9 per cent sodium chloride to the third.

Invert each tube to mix the contents thoroughly, and note the rapid agglutination and precipitation of the blood corpuscles in the first tube, a less

<sup>19</sup> The scarlet runner is a familiar variety purchasable in every seed store. It occurs in two varieties, the *white* and the *red*. Ricin, a protein constituent of the castor bean, also possesses pronounced agglutinating properties. Because of its poisonous nature it is, however, not suitable for use in class experiments.

<sup>20</sup> Rabbit's blood is especially desirable and may be obtained for the purpose by bleeding from a small cut on the animal's ear and defibrinating.

rapid agglutination in the second, while the third or control tube remains unaltered. In half an hour the corpuscles in the first tube often are packed solid and one is able to pour off perfectly clear serum.

If the remainder of the bean extract is boiled for a few minutes, the coagulum filtered out and 0.05 ml. of the filtrate added to the control tube, no agglutination occurs, indicating that the hemagglutinin has been destroyed or removed by the boiling.

**9. Red Cell Fragility.** When red cells are placed in a hypotonic saline solution, water passes into the cell until the osmotic pressure within and without are equalized. This brings about a swelling of the red cell which if sufficiently great causes the cell membrane to rupture, thereby resulting in hemolysis. Normal erythrocytes remain intact in as low as 0.44 per cent saline, whereas defective red cells, present in certain types of disease such as hereditary hemolytic jaundice, show beginning hemolysis at this concentration and complete hemolysis at 0.34 per cent.

**Procedure.** Prepare a 1 per cent solution of sodium chloride and from this make a series of dilutions ranging from 0.30 to 0.58 per cent by placing 0.60 ml. in the first test tube and 0.64 ml. in the second, increasing each successive tube by 0.04 ml. until the fifteenth, to which 1.16 ml. is added. Add distilled water to each tube to bring the volume to 2 ml. To each tube add one drop of blood obtained by venipuncture. Mix and allow to stand at room temperature for 2 hours. Record as beginning hemolysis the tube showing a slight tinge of red in the supernatant, and as complete hemolysis, the tube in which all cells have disappeared.

**10. Crystallization of Oxyhemoglobin (Reichert's Method).** Add to 5 ml. of the blood of the dog, horse, guinea pig, or rat, before or after laking or defibrinating, from 1 to 5 per cent of ammonium oxalate in substance. Place a drop of this oxalated blood on a slide and examine under the microscope. The crystals of oxyhemoglobin will be seen to form at once near the margin of the drop, and in a few minutes the entire drop may be a solid mass of crystals. Compare the crystals with those shown in Figs. 107 and 108, p. 472.

In some species (e.g., the rat) oxyhemoglobin tends to crystallize out of blood very rapidly. Merely pressing a small drop of blood between a coverglass and a microscope slide will result in a mass of oxyhemoglobin crystals.

**11. Preparation of Hemoglobin (Method of Marshall and Welker).** Draw blood into a flask and defibrinate by shaking with glass beads. Strain through cheesecloth. Centrifuge. Wash corpuscles three or four times with 0.9 per cent NaCl. Add ether a few drops at a time with thorough mixing until a clear solution is obtained. If the solution is viscid add a little water and then an equal volume of aluminum hydroxide cream (see Appendix). Mix thoroughly and filter. Cool to 0° C. and add absolute alcohol (also cooled to 0°) to make the alcohol percentage 20 to 30 per cent. Let stand at a few degrees below 0° C. Wash the crystals by decantation with 25 per cent alcohol at 0° C. Dry in a desiccator over sulfuric acid.

## **12. Demonstrations of Hemolysis and Osmotic Pressure.**

(a) **HEMOLYSIS (LAKING BLOOD).** Note the opacity of ordinary defibrinated blood. Place a few ml. of this blood in a test tube and add water, a little at a time, until the blood is rendered transparent. Hemolysis has taken place. How does the water act in causing this transparency? Examine a drop of

hemolyzed blood under the microscope. How does its microscopical appearance differ from that of unaltered blood? What other agents may be used to bring about hemolysis?

(b) OSMOTIC PRESSURE. Place a few ml. of blood in each of three test tubes. Hemolyze the blood in the first tube according to directions given in (a), above. Add an equal volume of isotonic (0.9 per cent) sodium chloride to the

FIG. 115. EFFECT OF WATER ON ERYTHROCYTES.

FIG. 116. CRENATED ERYTHROCYTES.

blood in the second tube, and an equal volume of 10 per cent sodium chloride to the blood in the third tube. Mix thoroughly by shaking, and after a few moments examine a drop from each of the three tubes under the microscope (see Figs. 115 and 116). What do you find and what is your explanation from the standpoint of osmotic pressure?

### PLASMA AND SERUM

Plasma is the noncellular fraction of the blood. It is conveniently obtained by centrifugation. If no anticoagulant is used, the plasma can be

designated as native. To obtain such plasma, it is best to collect the blood with a silicone-coated syringe and needle<sup>21</sup> and to transfer it to a tube similarly coated. Usually sodium citrate or oxalate is mixed with the blood to make it incoagulable. It is customary to name the plasma according to the anticoagulant employed, as for instance, oxalated, citrated, or heparin plasma.

Serum is the fluid obtained after blood has clotted. It has essentially the same composition as plasma except that it lacks fibrinogen and has a diminished concentration of various clotting factors.

**1. Preparation of Oxalated Plasma.** Collect 9 ml. of blood by venipuncture and mix immediately with 1 ml. of 0.1 M sodium oxalate<sup>22</sup> in a test tube or centrifuge tube. Centrifuge at 2500 r.p.m. for 5 minutes. Remove the plasma with a pipet. By attaching the rubber bulb of a medicine dropper to the pipet, the plasma can readily be drawn off.

**2. Preparation of Serum.** Place approximately 5 ml. of freshly drawn blood in a small test tube. Put the tube in a water bath at 37° C. for 30 minutes and then centrifuge at 2500 r.p.m. for 10 minutes.

**3. Separation of Fibrinogen, Globulin, and Albumin.** Add 0.5 ml. of half-saturated ammonium sulfate<sup>23</sup> to 0.5 ml. of oxalated plasma. Note the amount of precipitated fibrinogen formed. Repeat adding 0.5 ml. of saturated sodium chloride<sup>24</sup> to 0.5 ml. of oxalated plasma. Compare the amounts of fibrinogen obtained by the two salting-out methods.

Repeat the experiment, adding half-saturated ammonium sulfate and saturated sodium chloride to equal volumes of serum. Why do the solutions remain clear?

To 0.5 ml. of serum add 0.5 ml. saturated ammonium sulfate and mix. A precipitate of globulin is formed. Remove the salted-out protein either by centrifugation or filtration. To the clear filtrate, add small quantities of powdered ammonium sulfate and note the formation of a precipitate, which is albumin.

Outline a scheme of separating fibrinogen, globulin, and albumin.

Test samples of the precipitated fibrinogen, globulin, and albumin with the biuret, Millon's, and Hopkins-Cole tests.

**4. Heat Coagulation of Plasma Proteins.** Transfer 0.5 ml. of plasma and 0.5 ml. of serum to separate tubes and place in a water bath at 60° C. Examine after 10 minutes. Serum remains clear because it does not contain fibrinogen. Gradually increase the temperature of the bath and note when heat coagulation appears in the serum.

---

<sup>21</sup> *Coating glass with silicone.* Dilute one volume of Silicone (methyl-chlorosilane-Dri-Film N 9987, General Electric) with 3 volumes of toluene. Thoroughly clean the glassware and dry. Cover the surface to be coated with the silicone solution. Pour off the excess and drain for 30 minutes. Rinse in warm running water and dry. To obtain a thorough coating, polish the surface with a nylon cloth and recoat several times.

<sup>22</sup> *Sodium oxalate, 0.1 M.* Dissolve 1.34 g. sodium oxalate (c.p.) in 100 ml. of distilled water.

<sup>23</sup> *Saturated ammonium sulfate.* Cover 90 g. of ammonium sulfate (c.p.) with 100 ml. of distilled water. Mix and allow to stand for 24 hours. The supernatant liquid is saturated. Dilute with distilled water to obtain any desired saturation.

<sup>24</sup> *Saturated sodium chloride.* Cover 40 g. with 100 ml. of distilled water, mix, and allow to stand 24 hours.

## BLOOD COAGULATION

**1. Clotting Time of Recalcified Plasma.** On adding calcium to citrated or oxalated plasma, clotting will occur. The probable over-all equation to express the reaction is:

How these factors interact is not known, but there is strong evidence that the composite reaction is essentially stoichiometric. The thromboplastin does not exist pre-formed in the blood but is the product of the interaction of a platelet constituent and thromboplastinogen. The relatively slow and small production of thromboplastin is the limiting factor in the reaction and is therefore the determinant of the clotting time of recalcified plasma. If blood is oxalated in a test tube coated with material giving a nonwetttable surface such as paraffin or silicone, the platelets are preserved and can be removed by high centrifugation. Plasma thus obtained clots much more slowly on recalcification.

**Procedure.** Transfer 0.1 ml. of oxalated plasma to a small test tube and place in a water bath at 37° C. Blow 0.2 ml. 0.01 M calcium chloride<sup>25</sup> into the plasma to attain instantaneous mixing, and time the clotting exactly with a stop watch. Examine the tube every 15 seconds by gently tilting to detect the exact moment the incipient clot appears. Normal human oxalated plasma collected in glass clots in 90 seconds to 120 seconds after recalcification.

To determine the effect of the removal of platelets on the clotting time, collect 10 ml. of blood by venipuncture. Transfer 0.5 ml. of 0.1 M sodium oxalate to a glass test tube and the same quantity to a test tube coated with paraffin. Add 4.5 ml. of blood to each tube and mix by inverting the tube after covering it with wax paper. Chill the blood by placing it in an ice bath for 10 minutes. Centrifuge the paraffin-coated test tube at 2,000 r.p.m. for 15 minutes, and the glass test tube at the same speed but only for 3 minutes. Determine the clotting time of both plasmas on recalcification by the method as outlined.

**2. Prothrombin Time.** The relative slowness with which oxalated plasma clots after recalcification is due to the small amount of available thromboplastin. By adding an excess quantity of a potent standardized thromboplastin reagent<sup>26</sup> such as is readily prepared from rabbit brain, and a fixed amount of calcium, the clotting time can be made a quantitative measure of the prothrombin concentration, since the calcium and thromboplastin are constants in the reaction.

**Procedure.** Transfer 0.1 ml. of oxalated plasma to a small test tube, add 0.1 ml. of thromboplastin reagent, and place in a water bath kept at 37° C. Blow 0.1 ml. of 0.01 M calcium chloride measured in a short pipet into the

<sup>25</sup> *Calcium chloride, 0.01 M.* Dissolve 0.11 g. in 100 ml. of distilled water.

<sup>26</sup> *Preparation of Thromboplastin Reagent.* Remove the brain of a freshly killed rabbit and clear of all visible blood vessels. Triturate the material in a mortar with 20 ml. acetone and 0.1 ml. 0.2 M sodium citrate to remove traces of calcium. Avoid vigorous grinding until the material becomes flaky. Pour off the spent acetone. Replace with 20 ml. of a fresh portion and again triturate. Repeat until the material is granular and nonadhesive. Filter by suction and dry at 37° C. for 30 minutes.

Mix 200 mg. of the acetone-dehydrated brain with 5 ml. 0.85 per cent sodium chloride and incubate at 50° C. for 20 minutes. Mix occasionally by blowing through with a pipet. Place in a water bath at 37° C. and allow to settle sufficiently to permit drawing the solution into a pipet.

mixture. Click the stop watch at the moment the calcium chloride is added and time accurately the appearance of the clot. This is best done by leaving the test tube in the water bath until shortly before clotting occurs, then holding the tube towards a good light, and tilting gently to note the incipient formation of fibrin. Normal fresh oxalated human plasma has a prothrombin time of 11½ to 12½ seconds. When the plasma is mixed with saline in varying proportions, the following values are obtained:

| <i>Dilution of Plasma</i> | <i>Concentration of Prothrombin</i> | <i>Prothrombin Time</i> |
|---------------------------|-------------------------------------|-------------------------|
|                           | <i>per cent</i>                     | <i>seconds</i>          |
| 0                         | 100                                 | 12                      |
| 4 to 5                    | 80                                  | 13                      |
| 3 to 5                    | 60                                  | 14                      |
| 2½ to 5                   | 50                                  | 15                      |
| 2 to 5                    | 40                                  | 17                      |
| 1½ to 5                   | 30                                  | 19½                     |
| 1 to 5                    | 20                                  | 24 to 26                |
| ½ to 5                    | 10                                  | 37 to 42                |

By means of a serological pipet graduated in 0.1 ml. prepare the above dilutions and determine the prothrombin time of each mixture.

3. *Preparation of Thrombin (Eagle).* Dilute 10 ml. of fresh citrated or oxalated plasma with 100 ml. of cold distilled water. Chill the mixture to about 5° C. in ice water and then bubble carbon dioxide gas through the solution for 5 to 10 minutes. Centrifuge off the precipitate and discard the supernatant fluid. Dissolve the residue in 10 ml. of 0.85 per cent sodium chloride solution and adjust the resulting solution to approximately pH 7.0 by the addition of sodium bicarbonate. Add to this final solution one-twentieth its volume of 0.1 M calcium chloride solution (1.1 per cent). Warm to 37° C. for a few minutes, insert a glass rod into the clot which forms and wrap the clot around the rod until all entrained fluid has been pressed out. Discard the clot, filter the remaining fluid, and store in the refrigerator. If kept cold, this thrombin solution is stable for about a week. Dried preparations of thrombin in sealed containers, which are stable indefinitely, may now be obtained from wholesale drug supply houses.

CLOTTING TIMES. When 0.1 ml. of this thrombin solution is added to 0.2 ml. of oxalated plasma, coagulation occurs in about 3 seconds. Prepare the following dilutions of thrombin with distilled water: 1:2, 1:5, 1:10, 1:20 and 1:40. Determine the thrombin time of each dilution as follows. Transfer 0.2 ml. of oxalated plasma to a test tube, place in a water bath at 37° C. Blow 0.1 ml. of the thrombin solution into the plasma and accurately determine the clotting time with a stop watch. To prepare a curve, plot the clotting times against the dilution of thrombin, taking the undiluted thrombin preparation as 100.

4. *Preparation of Fibrin.* Allow blood to flow directly from the animal into a vessel and rapidly whip it by means of a bundle of twigs, a mass of strong cords, or a specially constructed beater. If a pure fibrin is desired it is not best to attempt to manipulate a large volume of blood at one time. After the fibrin has been collected it should be freed from any adhering blood clots

and washed in water to remove further traces of blood. The pure product should be very light in color. It may be preserved under glycerol, dilute alcohol, or chloroform water.

(a) SOLUBILITY. Try the solubility of small shreds of freshly prepared fibrin in water, dilute acid, and alkali.

(b) PROTEIN COLOR TESTS. Test a portion of fibrin by Millon's test, the Hopkins-Cole test, and the biuret reaction. What amino acids have you shown to be present in fibrin?

### SPECTROSCOPIC EXAMINATION OF BLOOD

As indicated in the text on p. 474, the spectroscope is a useful tool in the study of the blood pigments because of the differences in light absorption

FIG. 117. DIAGRAMMATIC REPRESENTATION OF SOLAR SPECTRUM.

Shown are approximate extent of colored zones and location of principal Fraunhofer lines (B, C, D, E, b, F, G).

which these pigments show, and which are evident upon spectroscopic examination. Fig. 117 shows a diagrammatic representation of the visible spectrum as seen with a spectroscope, including the approximate location and width of the various colored zones of the spectrum. If a solution containing a colored substance is placed between the spectroscope and the source of light, one or more dark zones or bands are seen in the spectrum, corresponding to the absorption of light of certain specific wavelengths by the colored substance. It is frequently possible to distinguish between various pigments by the location and intensity of these absorption bands.

FIG. 118. DIRECT-VISION SPECTROSCOPE.

Since the ordinary hand spectroscope is not equipped with a wavelength scale, the absorption bands may be located by reference to certain of the more prominent *Fraunhofer lines* of the sun's spectrum. These are *dark lines*, readily visible in the spectrum of sunlight, which correspond to the presence of certain elements in the vapors surrounding the sun. As shown in Fig. 117, the most prominent lines and their approximate wavelengths are as follows: B, 687m $\mu$ ; C, 656m $\mu$ ; D, 589m $\mu$ ; E, 527m $\mu$ ; b, 517m $\mu$ ; F, 486m $\mu$ ; G, 431m $\mu$ .

FIG. 119. ANGULAR-VISION SPECTROMETER.

FIG. 120. DIAGRAM OF ANGULAR-VISION SPECTROSCOPE (LONG).

The white light, *F*, enters the collimator tube through a narrow slit and passes to the prism, *P*, which has the power of refracting and dispersing the light. The rays then pass to the double convex lens of the ocular tube and are deflected to the eyepiece, *E*. The dotted lines show the magnified virtual image which is formed. The third tube contains a scale whose image is reflected into the ocular and shown with the spectrum. Between the light, *F*, and the collimator slit is placed a cell to hold the solution undergoing examination.

Either the *direct-vision* spectroscope (Fig. 118) or the *angular-vision* spectroscope (Figs. 119 and 120) may be used in making the spectroscopic examination of the blood. For a complete description of these instruments the student is referred to any standard textbook of physics or to the catalogs of the manufacturers.

1. *Oxyhemoglobin*. Examine dilute (1:50) defibrinated blood spectroscopically. Note the broad absorption band between D and E. Continue the dilution until this single broad band gives place to two narrow bands, the one nearer the D line being the narrower. These are the typical absorption bands of oxyhemoglobin obtained from dilute solutions of blood. Now dilute the blood very freely and note that the bands gradually become narrower and, if the dilution is sufficiently great, finally disappear entirely.

2. *Hemoglobin (So-called Reduced Hemoglobin)*. To blood which has been diluted sufficiently to show well-defined oxyhemoglobin absorption bands, add a small amount of Stokes's reagent.<sup>27</sup> The blood immediately changes in color from a bright red to violet-red. The oxyhemoglobin has been reduced through the action of Stokes's reagent and reduced hemoglobin has been formed, by the removal of the oxygen from the oxyhemoglobin. Examine this solution spectroscopically. Note that in place of the two absorption bands of oxyhemoglobin we now have a single broad band lying almost entirely between D and E. This is the typical spectrum of hemoglobin. If the solution showing this spectrum be shaken in the air for a few moments, it will again assume the bright red color of oxyhemoglobin and show the characteristic spectrum of that pigment.

3. *Carbon Monoxide Hemoglobin*. The preparation of this pigment may be easily accomplished by passing ordinary illuminating gas<sup>28</sup> through defibrinated ox blood. Blood thus treated assumes a brighter tint (carmine) than that imparted by oxyhemoglobin. Examine the carbon monoxide hemoglobin solution spectroscopically. Observe that the spectrum of this substance resembles the spectrum of oxyhemoglobin in showing two absorption bands between D and E. The bands of carbon monoxide hemoglobin, however, are somewhat nearer the violet end of the spectrum. Add some Stokes's reagent to the solution and again examine spectroscopically. Note that the position and intensity of the absorption bands remain unaltered.

The following are delicate chemical tests for the detection of carbon monoxide hemoglobin:

**ALKALI TEST.** Mix two drops of the suspected blood on a porcelain plate with an equal volume of 25 per cent NaOH. A reddish color remains in the presence of carbon monoxide hemoglobin. Treat two drops of normal blood in the same way. A brownish color is obtained.

**TANNIN TEST.** Divide the blood to be tested into two portions and dilute each with 4 volumes of distilled water. Place the diluted blood mixtures in two small flasks or large test tubes and add 20 drops of a 10 per cent solution of potassium ferricyanide.<sup>29</sup> Allow both solutions to stand for a few minutes, then stopper the vessels and shake one vigorously for 10 to 15 minutes, occasionally removing the stopper to permit air to enter the vessel.<sup>30</sup> Add 5 to 10 drops of ammonium sulfide (yellow) and 10 ml. of a 10 per cent solution of tannin to each flask. The contents of the shaken flask will soon exhibit the formation of a dirty olive-green precipitate, whereas the flask which was not shaken and which, therefore, still contains carbon monoxide hemoglobin will exhibit a bright red precipitate, characteristic of carbon monoxide hemoglobin. This test is more delicate than the spectroscopic test and serves to

<sup>27</sup> See Appendix.

<sup>28</sup> The so-called water gas with which ordinary illuminating gas is diluted contains usually as much as 20 per cent of carbon monoxide (CO).

<sup>29</sup> This transforms the oxyhemoglobin into methemoglobin, which does not combine with carbon monoxide.

<sup>30</sup> This is done to dissipate any carbon monoxide present.

detect the presence of as low a content as 5 per cent of carbon monoxide hemoglobin.

**DILUTION TEST.** In very dilute solution oxyhemoglobin appears yellowish-red, while carbon monoxide hemoglobin under the same conditions appears pinkish- or bluish-red. Dilute a drop of normal blood with water, and dilute in parallel fashion a drop of blood containing carbon monoxide hemoglobin with water, until by comparison a difference in tint is noted. This is said to be as satisfactory a test as any for routine purposes.

**QUANTITATIVE DETERMINATION OF CARBON MONOXIDE.**<sup>31</sup> If possible collect blood from an arm vein in an oxalated tube. Otherwise wrap a finger of the subject with a rubber band. Prick deeply with a blood lancet. Draw 0.1 ml. of blood into a pipet and discharge into a test tube containing 0.9 ml. of distilled water, drawing back once or twice to insure removal of adhering blood. Mix immediately but not too vigorously. Add 1 ml. of freshly prepared pyrogallic-tannic acid solution<sup>32</sup> and mix by inverting twice. After 15 minutes compare with standards prepared as follows: Take 1 volume of oxalated human blood free from carbon monoxide with 9 volumes of distilled water. Saturate half of the laked blood with CO by rotating in a flask or separatory funnel filled with illuminating gas for 15 to 20 minutes, avoiding violent agitation. Mix proportional parts of the treated and untreated blood solutions to represent 0, 10, 20, 30, 40, . . . 100 per cent saturation. Transfer 1-ml. portions of these solutions to test tubes of the same size as that used in the test. Add 1 ml. of freshly prepared pyrogallic-tannic acid solution to each and mix by inversion. Cover with a layer of melted paraffin and fill the remainder of the tubes with sealing wax. These standards are said to be permanent.

**4. Neutral Methemoglobin.** Dilute a little defibrinated blood (1:10) and add a few drops of freshly prepared 10 per cent solution of potassium ferricyanide. Shake this mixture and observe that the bright red color of the blood is displaced by a brownish red. Now dilute a little of this solution and examine it spectroscopically. Note the single, very dark absorption band lying to the left of D, and, if the dilution is sufficiently great, also observe the two rather faint bands lying between D and E in somewhat similar positions to those occupied by the absorption bands of oxyhemoglobin. Add a few drops of Stokes's reagent to the methemoglobin solution while it is in position before the spectroscope and note the immediate appearance of the oxyhemoglobin spectrum which is quickly followed by that of hemoglobin.

**5. Alkaline Methemoglobin.** Render a neutral solution of methemoglobin, such as that used in Exp. 4, above, slightly alkaline with a few drops of ammonia. Owing to the formation of alkaline methemoglobin the solution becomes redder in color and shows a spectrum different from that of the neutral solution. In this case we have a band on either side of D, the one nearer the red end of the spectrum being much the fainter. A third band, darker than either of those mentioned, lies between D and E somewhat nearer E.

## DETECTION OF BLOOD STAINS ON CLOTH, ETC.

**1. Identification of Corpuscles.** If the stain under examination is on cloth, a portion should be extracted with a few drops of glycerol or physiological

<sup>31</sup> Sayers and Yant: *Bureau of Mines Technical Paper 373* (1925). These authors describe a compact field apparatus. For gasometric determination of carbon monoxide in blood see Chapter 24.

<sup>32</sup> Made by dissolving 2 g. pyrogalllic acid and 2 g. of tannic acid in 100 ml. of distilled water.

(0.9 per cent) sodium chloride solution. A drop of this solution should then be examined under the microscope to determine if corpuscles are present.

**2. Tests on Aqueous Extract.** A second portion of the stain should be extracted with a few drops of water and the following tests made upon the aqueous extract:

(a) **HEMOCHROMOGEN.** Make a small amount of the extract alkaline by potassium hydroxide or sodium hydroxide, and heat until a brownish-green color results. Cool and add a few drops of ammonium sulfide or Stokes's reagent (Appendix) and make a spectroscopic examination. Hankin has suggested a test based upon the formation of cyanhemochromogen and the microspectroscopic demonstration of the spectrum of this compound.

(b) **HEMIN TEST.** Make this test upon a small drop of aqueous extract according to the directions given on p. 483, or, better, make the test upon a little material scraped from the cloth and put directly on a slide.

(c) **GUAIAC TEST.** Make this test on the aqueous extract according to the directions given on p. 484. The guaiac solution may also be applied directly to the stain without previous extraction in the following manner: Moisten the stain with water, and after allowing it to stand several minutes, add an alcoholic solution of guaiac (strength about 1:60) and a little hydrogen peroxide or old turpentine. The customary blue color will be observed in the presence of blood.

(d) **BENZIDINE REACTION.** Make this test according to directions given on p. 484.

## 23

# Blood Analysis: Colorimetry and Photometry

The factors which influence the chemical composition of the blood in disease may be broadly classified as physical and metabolic. The former include those cases of retention due to alteration or destruction of permeable membranes in the excretory organs, such as the lungs, kidneys, and liver. The accumulation of nitrogenous waste products in certain forms of nephritis, and the hypercholesterolemia associated with obstruction of the biliary ducts by gallstones, are examples of retention brought about by such processes. In the so-called metabolic diseases alteration in the chemistry of the blood may be induced by increased or diminished formation or utilization of the various constituents. Thus the accumulation of glucose in the blood as a result of metabolic derangement is an outstanding feature of diabetes mellitus. In chronic nephritis with edema (nephrosis), the high cholesterol values are considered to be of metabolic origin. Without multiplying examples, suffice it to say that changes in the blood chemistry need not be anticipated unless some condition affecting formation, utilization, or elimination is suspected. It is noteworthy, however, that the line of demarcation between these factors cannot be drawn very sharply. For example, both metabolic and mechanical factors are probably at work in renal diseases. In this connection it is important to differentiate between cause and effect. For example, the evidence that gallstones are the result and not the cause of hypercholesterolemia is not complete.

The present status of clinical chemistry is largely the result of the development of methods for the satisfactory analysis of small amounts of blood. Prior to the advent of modern micromethods for blood analysis, quantitative knowledge of metabolic processes within the body was based primarily upon analysis of the diet and urine by the classical methods of analytical chemistry. This came about because the amounts of blood required for analysis by similar methods were so large as to preclude the routine use of blood analysis for clinical purposes, except for such isolated instances as the determination of hemoglobin. Shortly after the first decade of this century, the pioneer work of such outstanding biochemists as Folin, Benedict, Van Slyke, Myers, and their associates and pupils and many others, in developing methods for the analysis of small amounts of blood by volumetric, colorimetric, and gasometric methods, initiated the present phase of quantitative clinical chemistry in which blood analysis has become an indispensable adjunct to the study of the functions of the body in both health and disease.

The variety of blood constituents for which quantitative methods are available and whose analytical determination is now almost routine in many hospital laboratories and elsewhere is illustrated by the accompanying table, which lists the normal concentration range for many of the major constituents of human blood, together with the chief instances in which pathological variation may be encountered. The blood of other species of animals may vary with respect to certain constituents; for example, in the rat, nonprotein nitrogen is distinctly higher, while sugar, urea, and chlorides are slightly so.

For the quantitative analysis of blood and other biological material, in many cases a number of different methods are available for the determination of the same substance. This is because the aim of biochemical workers to evolve methods which are specific for the substances being determined has not always been successfully accomplished. Many methods have undergone (and are still undergoing) a process of evolution toward this goal. The early blood sugar methods, for example, were relatively nonspecific and gave values of 100 to 120 mg. of glucose per 100 ml. of blood in normal individuals. Later methods, by eliminating the effect of nonglucose reducing substances, give values lower by about 20 mg. per cent or more, and presumably nearer the true glucose content. Thus the "normal" value may depend to a great extent upon the method used, and knowledge of the method employed is essential in interpreting the significance of values obtained, particularly in the earlier literature. The obvious value of more specific methods cannot be underestimated, but for many purposes if an older and simpler but less specific method provides a guide to blood changes in pathological conditions, its usefulness continues.

Because of the large number of methods which have been described in the literature, in a number of cases for the same substance, the choice of methods described in this chapter is somewhat arbitrary. The authors have selected those methods which they believe to be most generally useful and satisfactory, the selection in practically all cases being based upon personal experience or contact with hospital and research laboratories. In many instances alternate methods are offered, to provide for differences of opinion concerning the relative status of methods, and for differences between laboratories in facilities available or the type of results required. Blood chemical methods differ considerably in the expense or complexity of the necessary apparatus, in the time required for preparation of reagents and the performance of the analysis, and in the degree of precision of the results obtained. These factors must be considered in the selection of a method. Certain methods, for example, are more adaptable than others to multiple determinations as required in large hospitals. For occasional clinical determinations where a relatively wider margin of error is admissible, some of the simpler but less accurate methods may be used. It is worthy of note, however, that the trend in modern clinical laboratories is toward more exact rather than less exact methods, since only in this way can the demands of modern medicine be met.

At the end of this chapter will be found a list of references to methods for the determination of blood constituents which are less commonly called for and which are not described in detail here or elsewhere in this

COMPOSITION OF HUMAN BLOOD

| Constituent                                               | Normal Range mg. per 100 ml.* | Pathological Conditions in Which Increases (Unless Otherwise Noted) May Be Encountered                                                                        |
|-----------------------------------------------------------|-------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Total solids, per cent. ....                              | 19-23                         | Anhydremia. Low in hydremic plethora and anemia.                                                                                                              |
| Total proteins (serum), per cent. ....                    | 6.5-8.2                       | See above. Low in nephritis with edema (nephrosis).                                                                                                           |
| Albumin (serum), per cent. ....                           | 4.6-6.7                       | Low in nephrosis.                                                                                                                                             |
| Globulin (serum), per cent. ....                          | 1.2-2.3                       | Nephrosis, anaphylactic conditions, malignancy, infections, muscular activity.                                                                                |
| Fibrinogen (plasma), per cent. ....                       | 0.3-0.6                       | Pneumonia, infections. Low in cirrhosis of liver, chloroform or phosphorus poisoning, typhoid fever.                                                          |
| Hemoglobin, per cent (Haden) ....                         | 15.6                          | Polycythemia. Low in primary and secondary anemia, chlorosis.                                                                                                 |
| Iron, as Fe. ....                                         | 52                            | See Hemoglobin.                                                                                                                                               |
| Copper. ....                                              | 0.05-0.25                     |                                                                                                                                                               |
| Total nitrogen, per cent. ....                            | 3.0-3.7                       | Varies chiefly with proteins (albumin, globulin, hemoglobin).                                                                                                 |
| Nonprotein N. ....                                        | 25-35                         | Nephritis, eclampsia, etc. See Urea N.                                                                                                                        |
| Urea N. ....                                              | 10-15                         | Chronic and acute nephritis, metallic poisoning, cardiac failure, intestinal or prostatic obstruction, some infectious diseases. Relatively low in nephrosis. |
| Uric acid. ....                                           | 2.0-3.5                       | Nephritis, gout, arthritis, eclampsia.                                                                                                                        |
| Creatinine. ....                                          | 1-2                           | Nephritis.                                                                                                                                                    |
| Creatine. ....                                            | 3-7                           | Terminal nephritis.                                                                                                                                           |
| Amino-acid N. ....                                        | 5-8                           | Leukemia, acute yellow atrophy of the liver, severe nephritis.                                                                                                |
| Ammonia N. ....                                           | 0.1-0.2                       | Terminal interstitial nephritis.                                                                                                                              |
| Undetermined N. ....                                      | 4-18                          | Eclampsia.                                                                                                                                                    |
| Glucose. ....                                             | 70-100                        | Diabetes, pregnancy, severe nephritis.                                                                                                                        |
| Total fatty acids. ....                                   | 290-420                       | Diabetes, nephritis.                                                                                                                                          |
| Cholesterol. ....                                         | 150-190                       | Diabetes, nephritis, nephrosis, biliary obstruction, pregnancy. Low in pernicious anemia.                                                                     |
| Lipide phosphorus. ....                                   | 12-14                         | Diabetes, nephritis, pregnancy. In anemia, low in plasma, high in cells.                                                                                      |
| Total acetone bodies (as acetone) ....                    | 0.8-5.0                       | Diabetes.                                                                                                                                                     |
| Acetone + acetoacetic acid (as acetone) ..                | 0.3-2.0                       | Diabetes.                                                                                                                                                     |
| β-Hydroxybutyric acid (as acetone) ....                   | 0.5-3.0                       | Diabetes.                                                                                                                                                     |
| Bilirubin. ....                                           | 0.1-0.25                      | Biliary obstruction, hemolytic anemias. Low in secondary anemia.                                                                                              |
| CO <sub>2</sub> capacity (plasma) vol. per cent. ....     | 55-75†                        | Respiratory diseases, tetany. Low in diabetes, nephritis.                                                                                                     |
| CO <sub>2</sub> content (arterial blood) vol. per cent. . | 45-55†                        | Respiratory diseases, tetany. Low in diabetes, nephritis.                                                                                                     |
| CO <sub>2</sub> content (venous blood) vol. per cent. .   | 50-60†                        | Respiratory diseases, tetany. Low in diabetes, nephritis.                                                                                                     |

## COLORIMETRY AND PHOTOMETRY

**Introduction.** Many methods for the quantitative analysis of blood, tissues, urine, and other biological material are based upon the production of colored solutions in such a way that the intensity or depth of color so obtained may be used as a measure of the concentration of substance being determined. Such use of color as an index of concentration has long been known to analytical chemists as the science of colorimetric analysis, or colorimetry, and the instrument used for color evaluation is called a colorimeter. These terms, while admittedly not precise, have the sanction of established usage, particularly when they refer to the very common type of color measurement in which the colored solution representing the substance in unknown concentration is brought by one means or another to exact color match with a suitable standard color. Until relatively recently this was the only practical method for colorimetric analysis, because the human eye is much more capable of establishing the presence or absence of exact color equivalence than it is of defining quantitative differences in color intensity in precise terms.

It is clear, however, from a knowledge of the physical nature of color, that color intensity may be established in terms of the degree of light absorption at specific regions or wavelengths in the visible spectrum. To take a simple example, a solution has a blue color because generally speaking it absorbs a lesser proportion of the blue components of the mixed white light passing through it than of any of the other colored components. Thus white light entering the solution will emerge in diminished intensity and have a preponderance of blue wavelengths. The darker the solution, i.e., the more intense the color, the greater must be the degree of light absorption at certain wavelengths, so that such light absorption may be used as a direct measure of color intensity. Analytical procedures based upon the direct measurement of color intensity in terms of light absorption at specific wavelengths are known as photometric procedures, and the instrument used is called a photometer. This usage is by no means universal, however, and there are many who continue to use the term "colorimetric" for methods based upon the production of colored solutions, regardless of the means by which the color intensity is established. To avoid confusion, it appears desirable to define a *colorimetric procedure* as one in which the colored solution representing the substance in unknown concentration is brought to exact color match with a standard color representing the substance in known concentration, while a *photometric procedure* is one based upon the direct measurement of color intensity in terms of the light-absorbing power of the solution at a specific region of the spectrum. Unlike colorimetric procedures, which are limited to the visible portion of the spectrum, the general principles of photometric procedures are as applicable to the absorption of radiant energy in

the ultraviolet and infrared portions of the spectrum as they are to absorption in the visible region, and increasing analytical use is being made of this fact. The use of *turbidity* and *fluorescence* for analytical purposes is discussed on pp. 533 to 537.

## COLORIMETRY

As defined above, colorimetry is based upon the matching of a colored solution representing an unknown concentration of the substance undergoing analysis with a standard color representing the substance in known concentration. The substance must therefore be either colored by itself or capable of undergoing reactions leading to the production of a color. Furthermore, the color intensity must be dependent upon the concentration, otherwise the color reaction is valueless for colorimetric purposes. A colorimetric procedure therefore involves three operations: (1) The preparation of the colored solution to represent the unknown, (2) the obtaining of a suitable standard color, and (3) color matching.

If the substance being determined is itself colored—as, for example, hemoglobin, carotene, certain inorganic ions, dyes, etc.—the preparation of the colored solution for analysis is usually relatively simple, and may involve merely appropriate dilution or concentration of the sample to produce a color of intensity suitable for comparison against a standard. Even under these conditions, however, it is often better to separate the colored compound from possible interfering colored or noncolored material prior to estimation. If the substance must undergo a series of reactions leading ultimately to the production of a color, it is of the utmost importance to recognize that the final color intensity may be influenced to a considerable extent not only by the concentration of unknown substance but also by the intermediate steps leading up to and including the development of the color. Such factors as the time of heating and cooling, order and rate of addition of reagents, whether the reagents are new or old, the time of standing and temperature of the solution during color development, the presence of nonchromogenic material such as neutral salts, and even the volume of solution in which the color reaction occurs, are all known to influence the final color intensity for a given amount of material in many if not all colorimetric procedures. For accurate and reproducible results, therefore, it is essential that all steps in a colorimetric procedure be carried out under conditions as carefully controlled as possible. In many cases the authors of colorimetric procedures have carefully specified the conditions for precise analysis, and these conditions should be followed without deviation.

The obtaining of a suitable standard color is obviously a most important phase of a colorimetric procedure. It may be stated without qualification that the most satisfactory standard color, and the one which should always be used for accurate results, is that obtained by treating a known concentration of the substance being determined by exactly the same procedure that is used for the unknown, at the same time, and under as nearly identical conditions as possible. Thus the final colors in standard and unknown will be due to the same substance, differing if at all only in intensity, and the many nonspecific factors already mentioned which

may influence color intensity will presumably affect the standard and unknown to exactly the same extent and will not influence analytical results based upon their comparison. All colorimetric procedures must be originally based upon the use of this type of primary standard, even though secondary standards may be used later, as discussed below. This results because there is no way to predict the relationship between color intensity and concentration except in terms of the color yielded by a known concentration of the substance.

It is assumed in the use of a standard color that if the standard and unknown exactly match in color intensity they represent equal concentrations of the substance being determined. In actual practice this may or may not be true. The standard usually contains the substance being determined in relatively pure solution; in the unknown, extraneous factors may be present which modify color intensity. Substances other than the one being determined may enter into the color reaction, and results will therefore be too high; the analytical problem under these conditions is to devise either a more specific color reaction or to find methods for eliminating nonspecific interfering substances, and much of the trend in colorimetric analysis has developed along these lines. Another type of interference which is less frequently recognized is the influence of non-chromogenic material present on the intensity of color produced by a given amount of chromogenic substance. This may be tested for by adding to the unknown a given amount of the pure substance, and measuring the resulting increment in color intensity. If this increment is greater or less than that known to represent the added amount of substance in pure solution, and there is no possibility of loss or destruction, then factors are present in the unknown which modify color intensity per unit concentration, and suitable correction must be made. This method of using an "internal standard," as it is sometimes called, does not prove that the total color yielded by the unknown is due to the substance being determined, but it does establish whether or not this substance is capable of giving a complete color reaction under the conditions of the analysis.

In some colorimetric procedures standard solutions are required containing substances which are expensive or difficult to obtain in the pure state (e.g., bilirubin, and at one time, creatinine), or which deteriorate rapidly on standing or may require unavailable technical skill and apparatus for standardization (e.g., hemoglobin). To provide for the routine use of colorimetric procedures based upon such standards, various "artificial" standards have been devised. In most instances these standards consist of stable colored solutions of dyes or inorganic salts, or of colored glass or gelatin. The color is selected by the investigator or manufacturer to correspond as closely as possible to that representing a known amount of the substance being determined. Examples of the use of artificial standards will be found in the Newcomer method for the determination of hemoglobin (p. 616), in the Benedict picrate method for the determination of urine sugar (p. 923), and elsewhere. In using such standards, the color in the solution being analyzed is developed by the usual procedure and then compared against the artificial standard or standards representing known amounts of material.

There are many difficulties in the way of obtaining accurate results with artificial standards. Aside from the technical problem of an exact color match—and few individuals agree with one another on this point—it has already been pointed out that color intensity depends not only upon concentration but also upon the technique of the analytical procedure. Therefore the intensity of color corresponding to a given amount of material being determined may vary from laboratory to laboratory. Furthermore, few colorimetric procedures result in the production of a color which does not show either an increase or a decrease in intensity on standing. Comparison against a simultaneously prepared standard which undergoes equivalent changes in color intensity will eliminate errors due to such changes; comparison against a stable standard will clearly give results which may depend largely upon the time of standing after color development, and careful control of this factor may therefore be necessary. With few exceptions, artificial standards are satisfactory only where approximate results are sufficient; they should never be used simply to relieve the analyst of the responsibility for preparing and maintaining an exact standard solution. If artificial standards are used, they should always be checked in one's own laboratory and with one's own reagents, to eliminate errors from inexact calibration, and this checking should be repeated at frequent intervals or when new reagents are prepared.

**Colorimeters.** Colorimeters are instruments used to facilitate the exact matching of two colored solutions. This matching may be done in a variety of ways, summarized as follows:

1. BY COMPARISON AGAINST A SERIES OF STANDARDS. The unknown colored solution is compared by inspection with a series of color standards representing the substance being determined in known and varying concentration. The concentration of the unknown is given by the concentration of the standard which it exactly matches. The colorimeter is simply a device for holding the standards and the unknown and for providing uniform conditions of illumination to facilitate exact color match. The method is simple and requires relatively inexpensive apparatus. Chief drawbacks include the labor of preparing and maintaining the standards, the possibility of error due to deterioration of standards already prepared, and the fact that the range and precision of the method are limited by the number of standards available. The method therefore finds greatest application where it is known that the scope of the analytical problem is limited to results within a certain range of concentration, and highest accuracy is not required. Examples of the use of this principle are found in the colorimetric determination of hydrogen-ion concentration (Chapter 1), in the Benedict picrate method for urine sugar (p. 923), and in an increasing number of "pocket," "bedside," and "field" analysis outfits available commercially for specific analytical purposes (see Fig. 121). In many instances these outfits are fitted with artificial permanent standards, usually of colored glass or gelatin, to eliminate the necessity of preparing a series of standards. The use of such artificial standards has already been discussed.

2. BY DUPLICATION OF COLOR. In this method a relatively concentrated standard solution is measured into a "blank" containing the same

reagents as used in the sample until the color matches that of the sample, after the volume of the standard has been brought up to the volume of the sample by the addition of distilled water and thoroughly mixed. The

FIG. 121. SLIDE COMPARATOR, FOR COLORIMETRIC COMPARISON AGAINST A SERIES OF STANDARDS.

Courtesy, W. A. Taylor Co.

volume of standard solution required to prepare the duplicate is a measure of the amount of test substance in the sample. Some authors call this method *colorimetric titration*.

FIG. 122. MYERS' TEST-TUBE COLORIMETER.

3. BY DILUTION TO COLOR MATCH. Either the unknown or the standard is diluted with water or other solvent until the two colors exactly match in intensity when compared under similar conditions of illumination and depth of solution through which the light passes. Thus if the unknown must be diluted to twice its original volume to match a given standard, its original concentration is assumed to have been twice that of the standard, and in general if two colored solutions differing only in concentration are brought to color match by diluting one of them, the original concentration of the diluted solution is equal to the concentration of the undiluted solution multiplied by the ratio of final to initial volumes for the diluted solution. Only the simplest of apparatus is required for this procedure; the colorimeter may consist of two graduated test tubes (Fig. 122) or cylinders of equal bore. In the Sahli "Hemoglobinometer" (see Fig. 161, p. 612), which exemplifies this type of color comparison, the blood sample is diluted in a graduated tube to match a permanent standard representing a

known concentration of hemoglobin; from the dilution required the hemoglobin content of the sample is directly determinable. Dilution colorimetry is somewhat tedious, being comparable to a volumetric titration to an arbitrary end point, but results with an error not exceeding 5 per cent may

be obtained with practice. A major disadvantage of the dilution procedure is that many colored solutions are affected by dilution out of direct proportion to the change in total volume, owing to the influence of such factors as neutral salt concentration, acidity, or even the relative amount of solvent itself on the color intensity. Thus a blue solution of copper sulfate on being diluted to twice its original volume will have its color intensity affected not only by the change in volume but also by the change in copper-ion activity ("degree of dissociation") brought about by the dilution. It cannot be assumed that the dilution procedure is accurate, therefore, unless it has been shown to be so experimentally.

4. BY VARYING THE DEPTH OF SOLUTION THROUGH WHICH THE LIGHT PASSES. This procedure is the basis of the common laboratory visual colorimeter, and is called the *balancing method* of color comparison. It is based upon what is commonly known as Beer's law, which for present purposes may be stated as follows:<sup>1</sup> the intensity or density of color in a solution is determined for a particular substance solely by the number of colored particles (molecules or ions) in the light path. For example, a 1 per cent solution of a dye viewed through a solution depth of 20 mm. should have the same color as a 2 per cent solution viewed through 10 mm. of solution, because there are the same number of colored molecules or ions in the light path in each instance. In other words, color density is directly proportional to the concentration of colored substance and the depth of solution through which the light passes. Stated mathematically, for a particular colored substance,

$$D = k \times c \times l$$

where  $D$  is the color intensity or density,  $k$  is the proportionality constant characteristic of the substance,  $c$  is the concentration of colored substance, and  $l$  is the length or depth of solution traversed by the light beam.

For two solutions of the same substance at different concentrations  $c_1$  and  $c_2$ , and depths of solution  $l_1$  and  $l_2$ ,

$$D_1 = k \times c_1 \times l_1$$

and

$$D_2 = k \times c_2 \times l_2$$

If  $l_1$  and  $l_2$  are varied so that the two solutions have the same color intensity (i.e.,  $D_1 = D_2$ ), which is what is done in colorimeters based upon this principle, then

$$k \times c_1 \times l_1 = k \times c_2 \times l_2$$

or, by transposing and canceling out  $k$ ,

$$\frac{c_1}{c_2} = \frac{l_2}{l_1}$$

Thus two different concentrations of the same colored substance are related inversely to the depths of solution required for color match. If one of these solutions is a standard of known concentration,  $C_s$ , adjusted

<sup>1</sup> See pp. 515 to 522 for a more detailed discussion of Beer's law.

to color match with the solution of unknown concentration,  $C_x$ , by varying the depth of solution (readings  $R_s$  and  $R_x$  respectively on the colorimeter), the equation becomes:

$$\frac{C_x}{C_s} = \frac{R_s}{R_x}$$

or

$$C_x = \frac{R_s}{R_x} \times C_s$$

i.e., the concentration of the unknown is given by the readings of standard and unknown and the concentration of the standard.

In using this equation, it must not be overlooked that the term *concentration* means *amount per unit volume*, hence a more exact form of the equation is as follows:

$$\frac{X}{V_x} = \frac{R_s}{R_x} \times \frac{S}{V_s}$$

or

$$X = \frac{R_s}{R_x} \times S \times \frac{V_x}{V_s}$$

where  $X$  and  $S$  are the actual amounts of substance present in volumes  $V_x$  and  $V_s$  of unknown and standard colored solutions respectively, and  $R_x$  and  $R_s$  are the colorimeter readings as before. This form of the equation is the fundamental one upon which are based all colorimetric procedures of the type described here. In most procedures the final volumes of unknown and standard are the same, and the volume factor  $V_x/V_s$  cancels out; results are then obtained primarily in terms of the actual amounts of substance present, and as a matter of fact the directions for most colorimetric procedures prescribe the taking of a definite amount rather than concentration of standard. In certain colorimetric procedures (e.g., the determination of creatinine in blood, p. 555) the volumes of standard and unknown differ, and in such cases these volumes must be substituted in the above equation.

The value of  $X$  as obtained by the above calculation represents the amount of material in the portion of sample actually taken for color development. To express results in terms of amount per 100 ml. of blood, for example,  $X$  must be multiplied by  $100/v$ , where  $v$  is the volume of blood in ml. which contained the material on which the color was developed. Thus if color development in a blood sugar determination is carried out on a 2-ml. portion of filtrate from the blood diluted tenfold in the preparation of the protein-free filtrate used for the actual analysis,  $v$  in this case equals 0.2, since the 2 ml. of filtrate represent 0.2 ml. of original blood.

In applying the above equations to colorimetric calculations, certain limitations must be noted. For mechanical, optical, and analytical reasons the inverse relationship between concentration and depth of solution at color match is in general not applicable over the entire length of the colorimeter scale, which is usually about 40 to 50 mm. long and graduated in millimeters. The standard is ordinarily selected to be of such

strength as to give a good intensity for color comparison at a depth of about 15 or 20 mm. It is a general rule that readings of an unknown which are less than half or more than double the reading of the standard are outside the range of application of Beer's law. The amount of sample taken for analysis is selected if possible so that the expected reading will come within this range relative to the standard reading; readings outside this range are regarded as approximations only, to be used as a guide for repeating the analysis on a more satisfactory aliquot of sample. In general, it is better to change the amount of sample analyzed so as to come within the range of the standard than to alter the standard, because the standard is usually so selected as to provide the most satisfactory intensity for color match; lighter or darker standards may give less accurate results. If the amount of sample available is limited, however, and it is known that unusually high or low values may be encountered, the analysis may be saved by routinely providing several standards at different concentrations, the unknown being compared against the standard which it most closely matches on inspection.

In some colorimetric procedures the range of inverse proportionality between scale reading and concentration is much less than that represented by the "half or double" rule. The authors of such procedures usually specify the reliable range of readings. If the deviation from Beer's law is systematic, it is sometimes possible to establish a table of corrected values, showing the relation between the observed readings and the amount present, thus extending the range of permissible readings. From what has been said concerning the various factors which influence color intensity, however, it is clear that such a table is highly empirical and usually reflects the conditions prevailing in one laboratory only. It should be checked at intervals for accurate results; this checking is particularly important if a table developed elsewhere is to be used.

The use of light filters or of a monochromatic light source is ordinarily unnecessary in colorimetric comparisons, and mixed white light is commonly used, since if standard and unknown contain the same colored substance, at color match light transmission must be the same at all wavelengths. If extraneous colored material is present (i.e., if the reagents themselves are colored), or if unknown and standard differ in *hue* as well as in *intensity*, properly selected light filters may considerably improve the precision of readings or the range of applicability of Beer's law. When artificial standards are used, uniform and reproducible illumination is particularly important, because such a standard may, for example, represent one concentration by daylight and a different concentration by artificial light.

Colorimeters constructed to utilize the relationship between depth of solution and concentration expressed in Beer's law usually consist of (a) a source of light (mirror or built-in electric lamp); (b) a pair of adjustable cups and plungers, for varying the depth of solution through which the light passes; (c) an optical arrangement for looking down through the plungers and for bringing into juxtaposition the two fields of light from the solutions being compared, to facilitate exact color match. Many

different commercial models are available.<sup>2</sup> The constructional details of one type are shown in Fig. 123, and other types are illustrated in Figs. 124 and 125. In the original colorimeter of this type, designed by Duboscq, the cups were fixed and the plungers were raised or lowered to vary depth of solution; in modern Duboscq-type colorimeters, the plungers are fixed and the cups are adjustable. The cups usually hold about 5 ml. of solution; micro-cups and plungers may be used for smaller volumes. Cups with flared tops are preferred over the straight-side type. Some types of cups leak when in contact with certain nonaqueous solvents such as chloroform, and are therefore unsuitable for such solvents unless sealed with a resistant cement. For illumination, the most satisfactory sources are north sky light or light from an electric lamp equipped with a "daylite" filter. In selecting a colorimeter, the choice should be determined largely by size and definition of the optical field and the evenness of its

illumination, excellence of mechanical and optical construction, and ease of operation and reading.

<sup>2</sup> The instruments manufactured by Klett Manufacturing Co., New York, Bausch and Lomb Optical Co., Rochester, N. Y., and American Optical Co., Buffalo, N. Y., are especially satisfactory in the authors' experience.

The general principles involved in the use of a Duboscq-type colorimeter are illustrated by the following experiments.

## EXPERIMENTS ON COLORIMETRY

**1. Preparation of Colorimeter for Use:** (a) **LIGHT SOURCE.** Place the colorimeter on a firm table with the mirror facing the light source. A north window or "daylite" lamp is best. Some colorimeters have a built-in electric lamp in the base; this is equally satisfactory. Look through the eyepiece of the colorimeter and note the appearance of the field, focusing if necessary to bring it into sharp definition. Adjust the mirror (or the lamp in the base) and note that the evenness and intensity of illumination can be varied at will by this adjustment. Adjust until the two halves of the field are approximately evenly illuminated, at maximum intensity. This is a preliminary adjustment only; final adjustment in an analysis must always be made with the standard, as described in Exp. 2.

(b) **CHECKING THE ZERO.** Place each cup, clean and dry,<sup>3</sup> on its rack beneath a plunger, and carefully rack up the cup until it comes in contact with the bottom of the plunger. Read the colorimeter scales; each should read 0.0. If they do not, locate the scale adjustment or its equivalent and adjust so that both scales read 0.0 when cup and plunger are in contact. Check by lowering the cups slightly, then raising to contact, and again reading. Now lower the cups and interchange them on the plungers. Again bring to contact with the plungers and read. Are the scales still in adjustment? It is common practice to mark one cup, as by wrapping a rubber band around it, so that accidental exchange will not occur.

**2. Use of Colorimeter for Comparing Two Solutions.** Obtain two colored solutions, a standard and an unknown, containing the same substance in slightly different concentrations. Half fill each cup with a portion of the standard, place the cups on the racks, and rack up carefully to contact with each plunger. This serves to displace air bubbles which may be trapped under the plunger. Get into the habit of routinely checking the zero at this point at the same time. Lower the cups until both scales read exactly 15.0. Look through the eyepiece. Adjust the light source carefully until the two halves of the field are as evenly illuminated as possible. Theoretically, the reading on each side is now 15.0; actually, there is as much error in this adjustment as in the subsequent reading of an unknown; therefore for precise results the solution on one side should now be read against the other side ("matching the standard against itself"). Leaving the left-hand cup set, lower the right-hand cup slightly to throw the two halves of the field out of balance, then raise the cup slowly while looking through the eyepiece, until the field appears exactly even. Note the right-hand scale reading. Repeat this process three or four more times, and average the readings. *This is the actual reading of the standard that is used in the calculations.*

When the reading of the standard in the right-hand cup has been established, remove this cup, discard its contents, and place a portion of the unknown in the cup. Holding the cup in the hand, run it up and down briefly on the right-hand plunger, thus rinsing cup and plunger with the unknown. Discard the cup contents and repeat the rinsing with a fresh portion. Finally half fill the cup with fresh unknown and replace it on the cup rack. Run it up carefully to contact with the plunger, to displace air bubbles, then lower it

<sup>3</sup> Use a fresh piece of soft, lintless paper (lens paper or "Kleenex") to wipe the bottom of each cup dry. Do not use a towel or handkerchief for this purpose.

until inspection through the eyepiece indicates color match. Make the reading, and repeat three or four times as described for the standard, averaging the readings. *The average result is the reading of the unknown.*

From the readings of standard and unknown, and the known concentration of the standard, the concentration of material in the unknown is calculated as follows:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{Concentration of Standard} = \text{Concentration of Unknown}$$

Note that in this calculation the readings of standard and unknown are both made on the same scale, i.e., the right-hand scale. The standard in the left-hand cup is set at 15.0 (or 20.0, or whatever value is specified) merely to establish a satisfactory color intensity for comparison purposes, and its reading does not enter into the calculations. As a matter of fact, some types of colorimeter do not have more than one scale. It is true that various other methods of reading a colorimeter have been proposed, but these are all subject to more error than the procedure described here.

In making colorimeter readings, it is good practice to rest the eyes frequently by looking up from the colorimeter, because the eyes tire easily and color discrimination becomes less acute. Make four or five independent readings and average them to minimize error; if one reading in the series is obviously quite different from the others it may be discarded in averaging. Best results are obtained if alternate readings are approached from above and below, and the hand removed from the instrument between readings, thus minimizing the tendency to return mechanically to the same reading.

**3. Influence of "Personal Error" on Colorimetry.** Repeat the above experiment, but after you have read the standard against itself, have another individual make independent readings, and compare results. How closely do you agree? Now read the unknown against the standard, and calculate the concentration of the unknown from your readings. Have the second person likewise read the unknown and calculate results from his readings. Is any difference in opinion concerning the readings reflected in the final results? In general, it is necessary for each analyst to make his own readings of both standard and unknown; in this way, differences of opinion as to precise color match do not influence results.

**4. Beer's Law.** Obtain a series of aqueous methylene blue solutions containing 0.004, 0.005, 0.010, 0.020, and 0.030 g. per liter respectively of the dye. Select the 0.010 g. per liter solution as a standard, and set at 15 mm. Match the standard against itself, making the readings as described in Exp. 2, and then read each of the other solutions against this standard. On a sheet of cross-section paper, plot the colorimeter readings on the y-axis against the concentration on the x-axis. Draw a smooth curve between the points. Now calculate by the use of Beer's law what the various readings should be for the determined reading of the standard. Plot these theoretical readings on the same graph, and connect the points by a smooth curve. Do the two curves overlap completely or do they diverge at any points? To what extent does this dye follow Beer's law under these conditions? How could you obtain accurate results in a colorimetric procedure which is known not to obey Beer's law?

Another way of plotting results is to plot the theoretical reading for a given concentration against the actual reading. A straight line indicates adherence to Beer's law. It is the general practice to obtain results by calculation based on Beer's law only if the unknown reading is not more than double or less than half the standard reading. Unknowns falling outside this range are repeated with more or less of the sample for analysis.

**5. Influence of Analytical Procedure on Color Intensity.** Into each of two small flasks place 20 ml. of standard ammonium sulfate solution containing 0.2 mg. of nitrogen (see p. 549). To one flask add 2 ml. of Nessler's reagent,<sup>4</sup> drop by drop, from a buret. (Because of its poisonous nature,<sup>5</sup> never use a pipet with Nessler's reagent.) Set aside, and to the second flask add 2 ml. of the Nessler reagent, as rapidly as possible. Mix by lateral shaking and set aside. After 10 minutes' standing, read one of the two solutions against itself in the colorimeter, and then read the second solution against the first. Do the readings indicate that the two solutions have the same concentration of ammonia? What must be done to ensure uniform results?

## PHOTOMETRY

Photometry, in the sense in which the term is understood in analytical chemistry, consists in the measurement of the light-transmitting power of a solution in order to determine the concentration of light-absorbing material present. For purposes of simplicity the term *light* is used in place of the more inclusive term *radiant energy*. It must be understood that the principles upon which photometry is based are as applicable to the transmission of energy in the ultraviolet or infrared portions of the spectrum as they are to transmission in the more commonly employed visible, or colored, spectrum (see Fig. 287, p. 1249, for a chart showing the spectral distribution of radiant energy).

The ability of a solution to transmit light is known as the transmittance,  $T$ , of the solution. Strictly speaking, *transmittance* is defined as the ratio of the intensity,  $I_2$ , of the light emerging from the cell containing the solution to the entering or incident light intensity,  $I_1$ , or

$$T = \frac{I_2}{I_1}$$

For photometric purposes, however, it is neither practical nor necessary to measure the incident light intensity and to define transmittance in this way. In a photometric procedure there is always a certain proportion of nonspecific light loss during passage through the solution due to reflection from glass surfaces, scattering, and absorption by the solvent, reagents, and even possibly by contaminating traces of the substance which is being determined. Any of these will obviously influence a single measurement but should be constant from one measurement to another, and may therefore be balanced out by defining transmittance in *relative terms*. Thus if we let  $T_{soln}$  be the (over-all) transmittance of a solution containing a light-absorbing material (the solute) and let  $T_{solv}$  be the (over-all)

<sup>4</sup> See Appendix.

<sup>5</sup> See Chapter 31 for a discussion of the chemistry of Nessler's reagent and the reaction with ammonia.

transmittance of a reference solution (the solvent), usually the colorless solvent or reagent blank, both solutions being examined under equivalent conditions of wavelength, incident light intensity, and depth of solution, then the ratio of the transmittance of the solution to that of the solvent (or reagent blank) is equal to  $T_s$ , the *transmittancy*<sup>5a</sup> of the sample, i.e.,

$$T_s = \frac{T_{soln}}{T_{solv}} = \text{Transmittancy}$$

In this way neither the intensity of the incident light nor the nonspecific light loss need be determined, and furthermore contaminating traces of the substance being determined, or reagents which are themselves colored, do not interfere in an analysis. The change in transmittance due to the presence of the substance is determined solely by the increase in light absorption above a level which is *arbitrarily taken as zero*. It is this possibility of ruling out error from blank light absorption which represents an outstanding advantage of photometric analysis over colorimetric analysis with the Duboscq-type colorimeter, where this cannot be carried out without the use of correction factors.

Transmittancy,  $T_s$ , is thus a relative measurement and is always less than 1.00 if light-absorbing material is present. It may be expressed numerically either as a decimal fraction or in terms of per cent, e.g., a transmittancy of 0.65 or 65 per cent. A more satisfactory way of expressing the transmittancy of a solution is in terms of its negative logarithm,<sup>6</sup>  $-\log T_s$ , known as the *absorbancy*,  $A_s$ , also designated as the optical density,  $D$ , or the extinction,  $E$ , of the solution.

$$A_s = -\log T_s = \log \frac{1}{T_s} = \text{Absorbancy}$$

The utility of this basis for defining light absorption, particularly for photometric purposes, will be presented subsequently.

**Determination of Transmittancy.** The light transmittancy of a solution is determined by the use of an instrument known as a photometer. Many varieties and designs of photometers have been described and are available commercially; regardless of design, the principle upon which all analytical photometers operate is fundamentally the same, and may be described as follows: Light of suitable wavelength is allowed to pass through a reference solution, usually the colorless solvent or reagent blank, held in a container of fixed dimensions known as a cuvette. The intensity of light emerging from the reference solution is established at an

<sup>5a</sup> It is felt by some that a distinction between *transmittance* and *transmittancy*, as defined here, is relatively unimportant. Until standardized nomenclature in this field becomes more universally adopted, one may find some authors or publications using one term and some the other when referring to photometric measurements.

<sup>6</sup> Some investigators, particularly in European laboratories, use the natural logarithm rather than the common logarithm, i.e.,  $-\ln T$  rather than  $-\log T$ . The choice is immaterial for photometric purposes but may lead to confusion in applying data obtained elsewhere. The relation between these two methods of expression is as follows:

$$-\log T = 0.4343 \times (-\ln T)$$

arbitrary value by any of the various methods described below, this value usually corresponding to a reading on the photometer scale of 0 optical density or 100 per cent transmittancy. The reference solution is then replaced by the solution whose transmittancy is to be determined, held in the same or a similar cuvette, and the emergent light intensity measured relative to that established for the reference solution; this relation gives the transmittancy of the solution under examination.

The intensity of light emerging from a solution may be established by either *visual*, *photographic*, or *photoelectric* (or equivalent) means; of these, the last is most common, most accurate, and has largely displaced the others. In a visual photometer, the emergent light beam is compared in intensity with a parallel reference beam of similar properties which is of arbitrary and adjustable intensity. The adjustment required to bring the reference beam to the same intensity as that emerging from the solution under examination is the measure of the emergent light intensity. Measurements are therefore influenced by the acuity of visual color-intensity discrimination, as in visual colorimetry. In the photographic plate method, the intensity of action of the emergent light on a photographic plate is compared with the action of light of relatively known and adjustable intensity under similar conditions. This procedure is tedious and has been used in the past largely for measurements in the ultraviolet and infrared portions of the spectrum, where the eye is insensitive. Much of the earlier data in the literature concerning light absorption in these regions of the spectrum is based on this method, but it has been superseded almost entirely by the use of light-sensitive devices such as the photoelectric cell or its equivalent.

Light intensity is determined photoelectrically by using photoelectric cells or similar light-sensitive devices which produce an electric current in proportion to the intensity of light striking their active surfaces. Two types in common use are (1) the photovoltaic cell ("plate type," "rectifier," or "barrier layer" cell) and (2) the photoemissive tube. A photovoltaic cell consists essentially of a metal plate coated with light-sensitive material (selenium, cuprous oxide) which is in turn coated with a thin transparent film of a metal such as gold or copper. Light passing through the transparent film sets up a flow of electrons in one direction ("rectified") which establishes a potential difference between the two poles of the cell, and causes a current to flow if the cell is in a suitable electric circuit. Because of the electrical characteristics of photovoltaic cells, the current is not suitable for amplification, but for ordinary light intensities it is sufficiently large to be registered on a microammeter or low sensitivity galvanometer, and many types of photometers employ such cells. Photoemissive tubes or phototubes are either evacuated or gas-filled tubes similar in appearance to radio tubes and containing a plate coated with some substance which emits electrons when light strikes it, the electrons traveling to a suitable anode under proper conditions. The intensity of incident light thus determines the flow of electrons through the tube, and hence the current in an external circuit. This current is very small but may be readily amplified, and photometers employing such tubes usually have an amplifier circuit. An advantage of phototubes is

that they may be obtained with wide ultraviolet and infrared sensitivity, which is not the case with the photovoltaic cell.

With photosensitive devices, change in current output is used as a measure of change in light intensity. If the current output is adjusted to an arbitrary value with the reference or blank solution in place in the photometer, then the transmittancy of an unknown solution is given by the ratio of current output for this solution as compared to that for the reference solution. It is assumed that the current output is strictly proportional to the light intensity; with well-designed photometers this is usually sufficiently true over the range of light intensity for which they are used. If it is not the case, there may be apparent deviation from the theoretical relation between transmittance and concentration as defined by Beer's law (see p. 516), and such photometers are usually worthless for analytical purposes. Since the transmittancy is measured in a photoelectric photometer in terms of current output rather than of actual light intensity, it has been proposed that in such instances the term *photometric density* be used for the value of  $-\log T_s$  rather than *optical density*. From a practical point of view this distinction is unimportant and will not be used here, but it serves to emphasize the point that the numerical value of the optical density for a given substance may be considerably influenced by the characteristics of the photometer used for the measurement.

Light absorption at specific wavelengths is an intrinsic property of many substances, e.g., hemoglobin and other colored compounds in the visible region of the spectrum, and many other compounds in the ultraviolet and infrared portions of the spectrum. It may therefore be used to characterize such substances, just as other physical constants are so used, in addition to its use in photometric analysis. The extinction at a specified wavelength for a unit amount of a particular substance in solution is known as the *specific extinction* or *extinction coefficient*; the amount is frequently defined as that present in a 1-cm. layer of solution containing 1 per cent of the substance (symbolized by  $E_{1\text{cm.}}^{1\%}$ ). If the concentration is expressed on a molar basis, the term *molar* (or *molecular*) *extinction* is used. These constants are of more value for characterizing the substance in terms of its optical properties than for actual use in photometric analysis, but if they are sufficiently reproducible they may be used for the latter purpose, since they define the relationship between concentration and light absorption for the particular substance under specified conditions.

**Beer's Law.** The transmittance of a solution containing light-absorbing material depends upon (a) the nature of the substance, (b) the wavelength of the light, and (c) the amount of light-absorbing material in the light path, this latter depending in turn upon the concentration of substance and the depth of solution through which the light passes. The relation between these various factors was first clearly established for *colored* solutions by Beer, and hence is known as Beer's law, also as the Bouguer-Beer or Lambert-Beer law.<sup>7</sup> This relation may be expressed as

---

<sup>7</sup> For a fuller discussion of the laws of Bouguer and Beer, see Mellon: *Analytical Absorption Spectroscopy*, New York, John Wiley & Sons, Inc., 1950.

follows: at a given wavelength,

$$T_i = 10^{-k \cdot l \cdot c}$$

where  $T_i$  is the internal transmittance,  $k$  is a constant characteristic of the substance,  $l$  is the length or depth of solution through which the light passes, and  $c$  is the concentration of light-absorbing material.  $T_i$  is defined as the ratio  $I/I_o$ , where  $I_o$  is the radiant energy entering the sample and  $I$  that incident upon the second surface of the cell (see Fig. 126). The equation is exponential because of the particular characteristics of light

FIG. 126. SCHEMATIC DIAGRAM SHOWING DERIVATION OF TRANSMITTANCE (RATIO  $I_2/I_1$ ).

Internal transmittance,  $T_i$ , is the ratio  $I/I_o$ ;  $l$  is the length or depth of the absorbing path in the sample.

absorption (see texts on physics for details); it may be converted to the more common logarithmic form by taking the logarithm of both sides, as follows:

$$\log T_i = -k \times l \times c$$

or

$$-\log T_i = k \times l \times c$$

These equations relating transmittance, concentration, and depth of solution, at a given wavelength, are the fundamental ones upon which photometric analysis is based.

As mentioned on p. 512, for photometric purposes it is more practical to define transmittance in relative terms, i.e., the ratio of the (over-all) transmittance of the solution,  $T_{soln}$ , to that of the solvent (or reagent blank),  $T_{solv}$ , equal to  $T_s$ , the transmittancy.  $T_s$  is not precisely equal to  $(T_i)_{soln}/(T_i)_{solv}$ , but with end plates having a refractive index not greater than 1.5, the error is usually negligible.

**Relation between Transmittance and Concentration.** If the transmittances (in practice, transmittancy,  $T_s$ , values) of a series of solutions of a particular substance in various known concentrations are determined, at a particular wavelength and constant depth of solution (the usual conditions in a photometric analysis), the resultant data relating transmittance to concentration may be plotted in any one of four different ways, as shown in Fig. 127. If the transmittancy is plotted directly against concentration on ordinary cross-section paper, the curve

of Fig. 127A is obtained. To obtain a straight line rather than a curve, and thus permit the accurate establishment of the relationship between transmittancy and concentration at only one or two concentrations instead of the many required for a curve, advantage is taken of the fact that in accordance with Beer's law the equation for the curve is:

$$\log T_s = -k' \times c$$

the constant depth of solution permitting the combination of  $l$  and  $k$  into  $k'$ . Thus if the *logarithm* of the transmittancy is plotted against concentration (Fig. 127B), or if transmittancy is plotted on the logarithmic

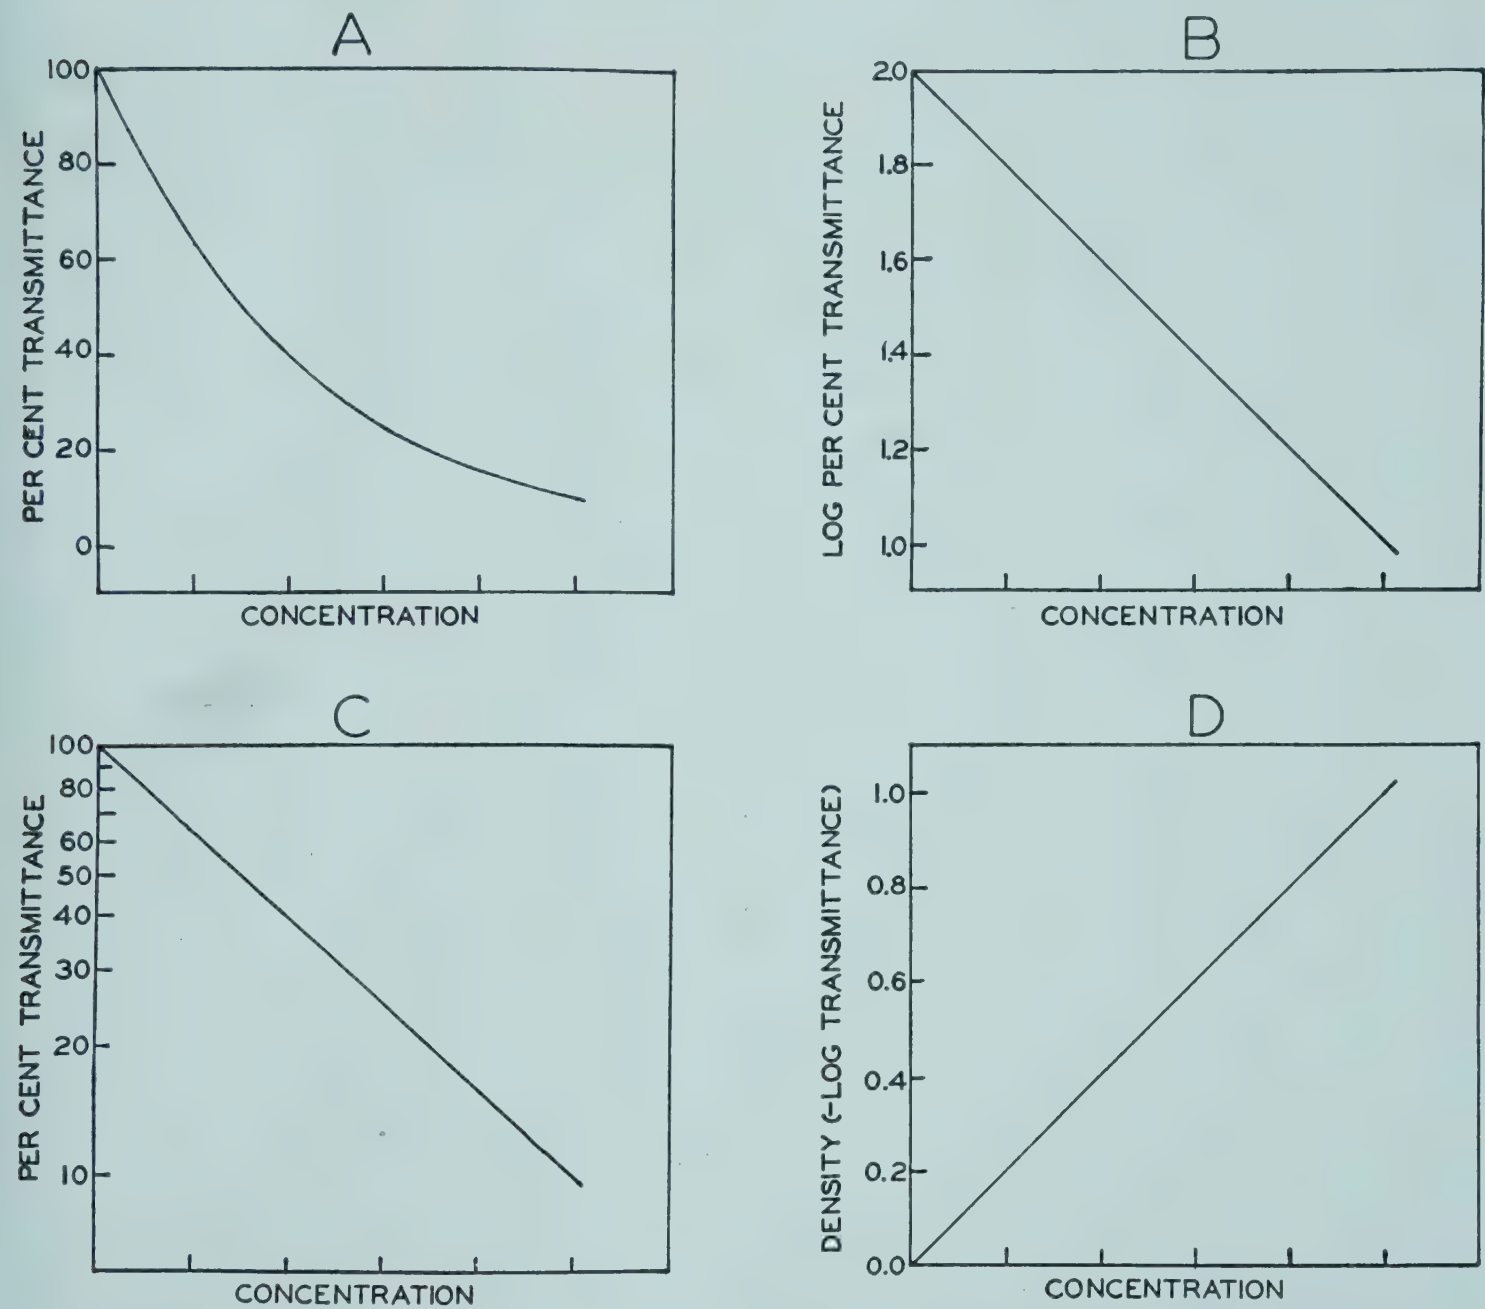

FIG. 127. VARIOUS WAYS OF SHOWING GRAPHICALLY THE RELATION BETWEEN LIGHT TRANSMITTANCE AND CONCENTRATION IN A PHOTOMETRIC PROCEDURE.

A, Per cent transmittance plotted directly against concentration. B, Log per cent transmittance against concentration. C, Per cent transmittance against concentration on semilogarithmic paper. D, Density ( $-\log$  transmittance, or  $2 - \log$  per cent transmittance) against concentration.

axis of semilogarithmic paper (Fig. 127C), straight lines with negative slopes will result. Finally, if the Beer's law equation is written as follows:

$$-\log T_s = k' \times c$$

and the values of  $-\log T_s$  plotted against  $c$ , a straight line with a positive slope results (Fig. 127D).

Of these four methods for relating transmittancy to concentration, the last is to be preferred. The quantity  $-\log T_s$  has already been defined as the optical density,  $D$ , of the solution. Where Beer's law is applicable, the optical density is *directly proportional to concentration*, or

$$D = k' \times c$$

This represents the simplest possible relation between light absorption and concentration, and it is the major advantage obtained by expressing transmittancy in terms of optical density rather than as per cent.

The established relationship between transmittancy and concentration for a particular analytical procedure is known as the calibration for that procedure. If this relationship is shown in the form of a graph, as in Fig. 127, the graph is called the calibration curve. Every analytical procedure requires a separate calibration, over a specified range of concentration and at a given wavelength and depth of solution; and in general the calibration established for one photometer is not applicable to another photometer, even of the same make. The most accurate way to establish the calibration for a particular procedure, and the one which should be used whenever possible, is in terms of the reading of a simultaneously prepared standard (or, in some instances, series of standards) for that procedure, just as in accurate visual colorimetry, and for the same reasons. In practically all of the common colorimetric or photometric procedures, the substance being determined is subjected to a series of reactions leading to the final production of a color which is used as the basis for estimation. The many factors *aside from concentration* which influence the final color intensity in most if not all colorimetric procedures have been discussed on p. 501 in connection with colorimetric analysis; they are of equal if not greater importance in photometry. Furthermore, since photometric measurements are ordinarily made individually and in a sense "against the instrument itself," rather than by comparison against a standard color, variations in mechanical, optical, and electrical properties of the photometer may likewise influence the calibration. Thus the calibration for a particular procedure may vary from day to day, from one photometer to another, and from laboratory to laboratory. If calibration is established in terms of the reading of a simultaneously prepared standard at the time the analysis is carried out, the various factors other than concentration which may influence the actual readings exert the same effect on the standard and on the solution being analyzed, and thus do not influence the relative evaluation of one in terms of the other.

To calibrate a procedure in terms of the reading of a simultaneously prepared standard, advantage is taken of the fact that optical density (or extinction) is directly proportional to concentration where Beer's law is applicable, as it is to practically all photometric procedures under the proper conditions. Therefore, for two solutions of the same substance at different concentrations, at the same wavelength and depth of solution, the relation between their respective densities,  $D_1$  and  $D_2$ , and concentrations,  $c_1$  and  $c_2$ , is as follows:

$$\frac{D_1}{D_2} = \frac{c_1}{c_2}$$

If one of these two solutions is a standard of known concentration and the other is of unknown concentration, then if their respective densities are measured, the concentration of the unknown is given by the calculation:

$$\text{Concentration of Unknown} = \frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{Concentration of Standard}$$

Thus the concentration of an unknown in a photometric procedure which shows agreement with Beer's law may be calculated from the determined density and the density of a known standard, and this method of obtaining results in a photometric analysis is used where applicable for all of the photometric procedures described in this chapter and elsewhere in this book.

The calculation is obviously quite similar to that used for visual colorimetric analysis with the Duboscq-type colorimeter (see p. 505), except for the direct instead of inverse proportionality between concentrations and readings. It is subject to the same limitations concerning the use of concentration rather than amount; if amount is used in the above equation rather than concentration, the unknown and standard must have the same total volume, otherwise the right-hand side of the equation is multiplied by  $V_x/V_s$ , where  $V_x$  is the total volume of unknown and  $V_s$  the volume of standard. To express results in terms of 100 ml. of blood, per liter of urine, or on some other arbitrary basis, the obtained result must be multiplied by a factor representing the relationship between the actual amount of sample used and the desired basis, as for colorimetric calculations.

To use this method of calculating results with photometers whose scale reads only in terms of per cent transmittancy, it is necessary to change the transmittancy value into its equivalent optical density. This may be done using a table of logarithms, or more simply by reference to the accompanying table, which gives the value of the optical density for all values of per cent transmittancy. Thus in an analysis, if the per cent transmittancy of standard and unknown are determined, readings are converted into density values by reference to the table, and results calculated as described above. If the photometer scale gives the density values directly, or reads in units which are proportional to density, the scale reading is used directly in the calculations. This is obviously more convenient, and a photometer scale of this type is to be preferred over one which is in terms of per cent transmittancy only.

Calculation of photometric results by the method described can of course be used only over the range of concentration where Beer's law is valid, i.e., where there is a linear relationship between optical density and concentration. For practically all photometric procedures in common use, conditions of wavelength, depth of solution, and concentration may be so selected that Beer's law is obeyed over the range of concentration apt to be encountered in an analysis. It is important in describing the details of a procedure to define these conditions, as has been done for the photometric procedures described in this chapter and elsewhere in this book.

RELATION BETWEEN TRANSMITTANCY ( $T_s$ ) AND OPTICAL DENSITY ( $D$ )

| $T_s$<br>(%) | $D$   | $T_s$<br>(%) | $D$   | $T_s$<br>(%) | $D$   | $T_s$<br>(%) | $D$   |

On photometers equipped with a linear scale reading from 0 to 100,  $D$  corresponds to the value of  $2 - \log G$  where  $G$  is the galvanometer or microammeter reading relative to an initial setting at the 100 mark.

For a few procedures, of which the determination of blood creatinine by the alkaline picrate reaction (p. 555) is an example, it is found that Beer's law is not followed under any analytical conditions. In such cases a calibration curve must be constructed and results obtained by reference to the curve as described below; for the most accurate results such a curve should be constructed with each series of analyses unless it is found to be highly reproducible. Instances of deviation from Beer's law are fortunately very rare. It is more common to find an apparent deviation from Beer's law when agreement is expected. This is usually the fault of the photometer. In most instances, agreement with Beer's law can be expected only when essentially monochromatic light is used, particularly when photovoltaic cells with their inherent varying spectral sensitivity are used in the photometer. If a wide rather than a narrow portion of the spectrum is used for measurement, as is unfortunately the case with some types of photometers, or if the photocell circuit is such that current output is not proportional to light intensity, the relationship between optical density (or  $-\log T_s$ ) and concentration will not be linear, and results

must be based upon a calibration curve. Photometers with such characteristics are therefore undesirable as a basis for accurate photometric analysis, because they do not permit the analytical precision associated with the application of Beer's law to the procedure.

Another commonly used method for obtaining results in a photometric analysis is based upon the use of previously prepared graphs of the type shown in Fig. 127, or of tables based upon the graphical data. The graph or table is established for a particular procedure by determining the transmittancy values for a sufficient number of solutions of known and varying concentration with respect to the substance being determined. In future analyses, the transmittancy of the solution of substance in unknown concentration is determined, and its concentration is then found from the graph or table, without running a standard at the same time ("colorimetry without standard solutions"). It is not necessary that the color reaction show agreement with Beer's law, since the relation between photometer reading and concentration is established empirically; this type of procedure therefore finds its greatest use where for one reason or another there is lack of agreement with Beer's law. An analogous procedure in instances where Beer's law is valid is to establish the density of a known standard and to use this value in future analyses, i.e., the concentration of the unknown is obtained by multiplying its determined density by a factor representing the established relationship between the standard and its density (see the photometric determination of hemoglobin, p. 610, for examples). The extinction coefficient of a substance may also be used in a similar way.

It is assumed in the use of such previously obtained calibration data that a particular transmittancy or density will always represent a particular concentration in an analysis. In practice this may or may not be true. The many factors which influence color intensity aside from concentration have already been emphasized. Even for substances such as hemoglobin in which the light-absorbing power is an integral property of the molecule itself, variations in environmental conditions or in the photometer itself may influence readings. Thus the use of a previously prepared calibration curve may be at best only an approximation, and gross errors are known to have resulted from its use. Colorimetry without standard solutions does not exist; the use of a previously prepared calibration curve simply represents a decision that the standard is to be prepared and read at one time and the unknown at some other time and possibly under different conditions, rather than that standard and unknown are to be prepared and read under the same conditions. It may be stated without equivocation that the greater desirability of the latter procedure has never been seriously challenged.

It is true that in some instances, as where the standard substance is difficult to obtain or maintain stable in solution, or the scope of the analytical problem permits the sacrifice of accuracy to convenience, a calibration curve may satisfy analytical requirements. If such a curve is used, it should be constructed in one's own laboratory using the reagents and photometer which will actually be employed in the analysis. Calibration data obtained from the literature or from the manufacturer of the pho-

tometer should never be used without checking, and this checking must be repeated at frequent intervals if satisfactory results are to be expected, particularly if there has been a change in the reagents or photometer. The analyses must be carried out with rigorous control of the various steps involved, reproducing as far as possible the conditions under which the curve was constructed. Only in this way can the occurrence of serious errors be prevented.

**Relation between Transmittancy and Wavelength.** The relation between the transmittancy (and hence the optical density) of a solution containing light-absorbing material and the wavelength of light passing through the solution is given by the so-called absorption spectrum of the substance. The absorption spectrum is established quantitatively by measuring the transmittancy for a particular concentration and depth of solution at various wavelengths, and plotting the results in the form of a

FIG. 128. A RELATIVELY SIMPLE ABSORPTION SPECTRUM.

Curve *b* represents a concentration twice as great as for curve *a*. The dotted line indicates the wavelength of maximum sensitivity for photometric measurement.

curve relating transmittancy or optical density (the latter is preferred) to wave-length. An example of a relatively simple absorption spectrum is shown in Fig. 128; more complex curves are frequently found. The absorption spectrum of a substance is usually characteristic of the substance and may serve for identification as well as furnishing information of analytical value. The application of absorption spectra is not limited to the visible region of the spectrum but may be applied equally well to characterization of the ultraviolet or infrared absorption of many substances.

For a particular substance, absorption curves at different concentrations will be generally similar in shape but will differ in their position along the transmittancy axis (curves *a* and *b* in Fig. 128). It will be noted that for a particular substance at a given concentration, there may be a certain amount of light absorption (transmittancy less than 100 per cent) at most wavelengths, but that this absorption is relatively greater in some spectral regions than in others. In the visible region of the spectrum, this difference in relative light absorption at various wavelengths is of course

the cause of *color*, since when white light containing all wavelengths passes through the solution, the emergent light contains a greater proportion of some wavelengths than of others, and hence appears colored.

As the concentration of substance in solution is increased (Curve *b* relative to Curve *a*) there is usually increased light absorption at all wavelengths where any light is absorbed at all, but this increase is usually greater per unit change in concentration at some wavelengths than at others. Thus the wavelength used may determine the relationship between concentration and optical density at a constant depth of solution (i.e., the numerical value of *k* in the Beer's law equation), and this is frequently a major factor in the choice of the proper wavelength for photometric measurement.

Maximum sensitivity in a photometric procedure is obtained at the wavelength where there is the greatest change in optical density or transmittancy per unit change in concentration. Most often, this is the wavelength of maximum light absorption, or *minimum* in the transmittancy curve (dotted line, Fig. 128). Occasionally, however, as for example in a procedure where the transmittancy curves for reagent and colored compound overlap considerably, the highest sensitivity may be obtained at a wavelength on one side of the absorption maximum. Thus, a knowledge of the absorption spectrum of both reagent and colored compound (the latter at two or more concentrations) is necessary for selection of the optimum wavelength.

Maximum sensitivity is not *per se* the chief consideration in the selection of the proper wavelength for photometric measurement. From an analytical point of view, the most satisfactory wavelength is the one which, at a given depth of solution, shows agreement with Beer's law over as wide a range as possible of the concentrations apt to be encountered in an analysis, and which permits this range to be read within the most accurate region of the photometer scale. The most accurate region of the scale corresponds to densities between about 0.2 and 1.0 (60 to 10 per cent transmittancy). Readings outside this range represent solutions which are either too light or too dark for the most accurate measurement; thus at 95 per cent transmittancy an absolute error of 0.5 per cent in the transmittancy measurement corresponds to a 10 per cent error in an analysis; and at the other end of the scale, for dark solutions unit change in transmittancy represents a disproportionately large change in concentration. The sample should therefore read between the scale limits specified if maximal accuracy is to be obtained.

To fulfill these requirements in the case of the Folin-Wu blood sugar method, for example (see p. 568), a wavelength may be selected which represents a very low sensitivity, so that the normal glucose standard representing 100 mg. per cent blood sugar will have a low light absorption. This would permit reading blood sugar values well above normal, which is the usual direction of change in this procedure, under the same conditions. If the usual direction of change is below the normal value, as in hemoglobin determinations, conditions are selected such that the normal sample has a high light absorption. In general, to adapt to photometric measurement a procedure which was originally developed for visual

colorimetry and hence may yield a more intense color than is required for photometric measurement, and in a larger volume of solution, it is better to modify the light absorption. This may be done by selection of a suitable wavelength or use of a small depth of solution rather than by such procedures as taking a smaller sample or diluting the final color, since these may seriously affect the accuracy. However, the greater sensitivity of photometric measurement, and the possibility of using very small volumes of solution, is obviously conducive to the development of microanalytical methods, of which many have been and are being developed, and this represents an important contribution of photometry to analytical chemistry.

Other factors which may influence the choice of wavelength for photometric measurement include the possibility that agreement with Beer's law will be found to be more satisfactory over a wider range of concentration at one wavelength than at another, or that the color will be more stable when exposed to light of one wavelength than to that of another. Even if such selection entails a decrease in sensitivity, the enhancement of the analytical value of the procedure may make the wavelength of lesser sensitivity the one of choice. If two or more light-absorbing substances are present together, and it is desired to measure the change in optical density related to variation in amount of only one of these substances, it is sometimes possible to select a wavelength at which there is only minimal light-absorption by extraneous material, and thus prevent such material from interfering significantly in an analysis. Such photometric separation is rarely complete; it is usually better to effect preliminary analytical separation, or to include the light absorption from extraneous material in the blank solution used for the initial setting of the photometer.

Knowledge of the complete spectral characteristics of a light-absorbing compound is of fundamental importance in defining the conditions under which satisfactory photometric analysis is possible. Wherever possible such information should be made available in the description of a photometric procedure, as has been done in many instances for the various photometric procedures described in this chapter and elsewhere in this book. The detailed description of the spectrophotometric characteristics of the Nessler reaction with ammonia, given in Chapter 31, illustrates the applicability of absorption spectrum data to photometric procedures.

**Light Filters and Filter Photometers.** The wavelength at which photometric measurements are made may be established either by the use of light filters or by the production of a complete spectrum and isolation of the desired portion. Instruments based upon the first principle are known as filter photometers; those based upon the second principle are called spectrophotometers (see p. 531). Most types of photometers in current use are filter photometers, though spectrophotometers are now extensively used, even for routine analyses. Filter photometers, however, are less expensive than spectrophotometers, require less technical skill in operation, and if well designed are just as satisfactory for most analytical purposes, particularly in the visible region of the spectrum. Except for special instances, spectrophotometers must ordinarily be used for photometry in the ultraviolet and infrared portions of the spectrum.

Light filters commonly consist of selected glass (or sometimes dyed gelatin) which is capable of transmitting light over a limited portion of the spectrum only. Thus by placing such a filter in the light path of the photometer, measurements may be made in the spectral region corresponding to the transmittance range of the filter. Various filters differ principally with regard to (a) the spectral region of light transmittance, and (b) the width of the transmitted band. By suitable selection of various types or combinations of glass, it is usually possible to obtain a filter whose transmittance is limited to almost any desired portion of the spectrum. A selection of such filters is illustrated in Fig. 129. Suitable filters may be obtained from the manufacturers of the photometer, or they may be constructed in the laboratory if suitable glass is available. It is customary to designate a filter in terms of the wavelength of peak

FIG. 129. LIGHT TRANSMITTANCE OF SELECTED LIGHT FILTERS.

Courtesy, Rubicon Co.

transmittance, thus a filter called “No. 540” or “No. 54” has its peak transmittance at a wavelength of 540 mμ. This practice is not universal, nor is the wavelength designation always accurate, and when a filter of any kind is used in a photometric procedure the wavelength of peak transmittance should be stated also. If this information is not known, it may usually be obtained from the manufacturer of the filter or glasses used. When the wavelength required for a particular photometric procedure is stated in the description of the procedure, as for example, “at 540 mμ,” this corresponds to the use in a filter photometer of a filter with a peak transmittance at this wavelength.

The most satisfactory filters are those which transmit as narrow a spectral region as possible, since this represents an approach to truly monochromatic light. A good filter for photometric purposes will show a transmittance of about 85 per cent or more of the total light transmitted over a spectral width of 30 to 60 mμ or so, centered around the wavelength of peak transmittance. This information concerning a filter may be obtained from its transmittance curve, as illustrated in Fig. 129. Filters with a broader range of transmittance are in general unsatisfactory, because they may result in apparent deviations from Beer’s law, as discussed on p. 520.

In recent years interference filters (metallic films on glass or fused quartz) have come into use, such as, for example, those made by Baird, Farrand, and others. The Farrand filters consist of evaporated thin layers of dielectric material between semitransparent metallic films on glass.

Interference filters are sometimes called *monochromatic filters* because of their band pass of only 20  $m\mu$  or less, much narrower than the usual glass or gelatin filters. These filters, however, are not monochromatic in the sense that light of a single wavelength is monochromatic, since they transmit a narrow range of wavelengths rather than a single wavelength.

Interference filters have a high transmission, being about 40 per cent—more than twice that possible with ordinary filters of equal band pass.

Representative types of filter photometers commercially available are illustrated in Figs. 130, 131, and 133. Many other types are on the market,<sup>8</sup> some of which are doubtless as satisfactory as those illustrated. The Hellige "Chromatron" (Fig. 130) is an example of the single photocell type of photometer, with built-in meter, the scale of which reads linearly from 0 to 100, and hence gives transmittancy in per cent. This instrument is designed for use with rectangular pyrex

FIG. 130. HELLIGE "CHROMATRON" PHOTOELECTRIC COLORIMETER.

cuvettes. The light source is mounted in a self-focusing housing and is operated below its rated wattage either from two dry-cell batteries or from an A.C. line through a built-in constant voltage transformer. The filters are mounted in a rotating disk close enough to the photocell to avoid interference from stray light. The photocell is hermetically sealed in an inert atmosphere. In operation, the instrument is adjusted to a scale reading of 100 with water and a suitable filter in place; the water is then replaced by the solution under examination, and the scale reading noted. This value gives the transmittancy of the sample, in per cent. To convert transmittancy into optical density, the value of  $2 - \log R$  is obtained, where  $R$  is the scale reading, or the table on p. 520 may be used. Users of this type of instrument appear to prefer the calibration curve method of obtaining results, rather than calculation based upon optical density. The Hellige instrument is also available in a model ("Clinicol") pre-calibrated for a variety of clinical procedures which are described in an accompanying handbook.

The Evelyn photoelectric colorimeter (Fig. 131) is likewise a single photocell photoelectric filter photometer, with uniform test tubes customarily employed as solution containers, and with readings made on a

<sup>8</sup> Manufacturers of satisfactory photometers include Central Scientific Co., Chicago; Rubicon Co., Philadelphia; Klett Manufacturing Co., New York; Fisher Scientific Co., Pittsburgh; American Instrument Co., Silver Springs, Md.; Coleman Instruments, Inc., Maywood, Ill.; Hellige, Inc., Garden City, N. Y.; Photovolt Corp., New York; Pfaltz and Bauer, New York; Bausch and Lomb Optical Co., Rochester; and others. Some of these concerns likewise manufacture fluorimeters. Information concerning various types available usually may be secured from any laboratory supply house.

sensitive galvanometer which is separated from the rest of the instrument. The galvanometer scale is graduated linearly, from 0 to 100, so that readings here are also in terms of per cent transmittancy. A diagram illustrating the schematic construction of the Evelyn instrument is shown in Fig. 132. With a suitable filter in place, the reference fluid in a special test tube is placed in the instrument and the light intensity adjusted by resistance control until the meter reads 100. The reference fluid is then replaced by the sample, in a second similar test tube, and the galvanometer reading noted. Its value gives the per cent transmittancy of the sample. To convert transmittancy into optical density, the value of  $2 - \log G$  is obtained, where  $G$  is the galvanometer reading; or the table on p. 520 may be used.

The light source is a 6-volt bulb, operated from a storage battery to provide constancy of illumination, which is essential with all single cell photometers. The filters used with this instrument are particularly satisfactory from the point of view of narrowness of spectral band; the selec-

tion available is shown in Fig. 129. The test tubes require a minimum of about 6 ml. of solution for a reading; a microcolorimeter, requiring much less fluid, is also available for use with the instrument. The use of test tubes as solution containers or cuvettes has the great advantage that many colorimetric procedures may be carried out partially or wholly in the same tube as will be used for the final reading. The Evelyn test tubes have dimensions such that they correspond roughly to a 2-cm. solution thickness, so that the optical density for a particular concentration of substance will be about twice that expected at 1-cm. depth, which is the usual basis of reference, and which is used throughout this chapter. This means that in the Evelyn instrument, a sensitivity and concentration range specified for 1-cm. solution depth will correspond to about twice the sensitivity, over the lower half of the specified concentration range only; higher concentrations will prove to be too dark to read accurately. This must be considered in interpreting data obtained by this instrument or for use with it.

The Bausch and Lomb "Monochromatic" Colorimeter is a single-photocell, direct-reading photoelectric colorimeter, equipped with narrow-band interference filters. (See p. 525.) A 6-volt, 32-c.p. incandescent lamp, operated from a constant voltage transformer, supplies the light for both the scale and the analysis path. Light from the lamp passes through condensing lenses, then through a heat-absorbing filter, past a control diaphragm, through an interference filter, and then through the sample solution, finally striking a barrier-layer photocell. The current output of the photocell is measured by a sensitive double-suspension galvanometer, the deflection of its mirror (indicated by a floating spotlight) being measured upon the translucent scale at the front of the colorimeter.

Advantages of single-photocell photometers such as the three just described include the simplicity of construction and the fact that readings are made on a direct-reading meter which does not require manual adjustment. Thus even relatively unstable colors, such as that obtained in the antimony trichloride reaction for vitamin A, may be read immediately or at successive small time intervals for extrapolation. The major disadvantage of the single-photocell type is the requirement for a stable light source, to eliminate the possibility of error due to a change from the initial light intensity during a measurement. To provide a constant current for the light source, storage batteries or constant-voltage transformers are used; the former is generally more satisfactory, since the efficiency of constant-voltage regulators may depend upon the type of power supply available. Another disadvantage of single-photocell photometers is that they usually incorporate meters designed primarily for current measurement and not for photometric purposes, with linear graduation and frequently a small total scale length, which may make precise reading difficult. Meters should be accurately readable to one-third of a scale division, for example, if a reading error of 1 per cent or less is expected over one-third of the scale range. Linear graduation of the scale requires the use of logarithms or conversion tables to convert per cent transmittancy values into optical density, which is a much more satisfactory basis for

photometric analysis. Some types of single-cell photometers are equipped with scales reading in terms of optical density as well as, or rather than, per cent transmittancy; it is not unreasonable to hope that this practice will be extended.

To overcome some of the disadvantages of single photocell photometers, various types of photometers employing two photocells in a balanced circuit have been developed, of which the Klett-Summerson instrument (Fig. 133) is an example. The details of construction of this instrument are shown in Fig. 134. In operation, with a suitable filter in place, the reference solution contained in a test tube is placed in the path of light striking one of the two photocells, which are arranged in a potentiometric circuit so that the current from one cell is opposed to that from the other through a null-point instrument (low-sensitivity galvanometer). With the photometer scale set at zero (corresponding to zero optical density) the current output from the second photocell is adjusted so that it exactly balances that coming from the photocell which is subject to the light emerging from the solution. This balance is indicated by a zero reading on the galvanometer. The reference solution is then removed and

Summerson, *J. Biol. Chem.*, **130**, 149 (1939).

replaced by the solution under examination. Any light absorption by this solution will throw the two photocells out of electrical balance; balance is then restored by turning the potentiometer dial until the galvanometer again reads zero. The reading on the potentiometer scale at this point is the measure of the light absorption of the solution.

The light source is a 100-watt bulb operated directly from an ordinary power supply; the balanced circuit prevents fluctuations in light intensity from influencing readings. The instrument is designed for use with light filters of relatively narrow spectral transmission; the selection available is similar to that shown in Fig. 129. The test tubes require about 5 ml. of solution for a reading; microtubes requiring about 2 ml. may also be used. The test tubes may be used for color development as well as for reading, and may be centrifuged if necessary. The effective solution depth is approximately 1 cm., so that photometric data based on this depth of solution are directly applicable to the instrument. Models permitting the use of glass cells at other solution depths are also available.

The scale on the Summerson instrument deserves comment, because it is somewhat unusual. It is graduated in units which are proportional to optical density; the actual numerical values represent the optical density divided by two and with the decimal point omitted. Thus a scale reading of 250 corresponds to an optical density of 0.500; of 100, to 0.200, and so on. In general, the relation between scale reading  $R$  and optical density  $D$  is as follows:

$$\frac{1000 \times D}{2} = R$$

Thus the fractional values of optical density (see table on p. 520) have been replaced by whole numbers, to facilitate use in photometric calculations. Since the scale readings bear a constant relation to optical density, they may be used directly in place of density values in the calculations of photometric analysis.

FIG. 135. PERKIN-ELMER FLAME PHOTOMETER.  
Courtesy, Perkin-Elmer Corp.

An interesting recent development in filter photometry is the flame photometer (Figs. 135 and 136).<sup>9</sup> This was designed primarily to facilitate the rapid and accurate analysis of such metallic elements as sodium and potassium, which have intense and characteristic flame spectra. The

<sup>9</sup> For a review of flame photometry, see Barnes, Richardson, Berry, and Hood: *Ind. Eng. Chem. Anal. Ed.*, **17**, 605 (1945). Also Berry, Chappell, and Barnes: *Ind. Eng. Chem. Anal. Ed.*, **18**, 19 (1946).

sample in solution is blown in the form of a fine spray into a colorless flame, and the intensity of the resulting flame spectrum is determined by the response of a photoelectric cell, as measured on a galvanometer or microammeter. The instrument is calibrated for a particular metal by running a series of standards containing varying concentrations of the metal ion. No ashing or other preliminary preparation of the sample is ordinarily required; sodium and potassium determinations on blood plasma or serum for example require merely appropriate dilution with water. This instrument is known to give excellent results, and has proved to be quite valuable in the particular analyses for which it is fitted.

**Spectrophotometers.** In place of using light filters for isolating the narrow spectral region usually required for photometric analysis, a device for producing the complete light spectrum and isolating the desired portion may be used. Instruments based upon this principle are known as spectrophotometers.<sup>10</sup> In the Beckman photoelectric spectrophotometer (Figs. 137 and 138), the spectrum is produced by the use of a quartz prism; a diffraction grating may also be used, as in the Coleman instrument (Fig. 139). The spectral band is focused on a narrow slit mounted in front of the solution being examined, and by shifting the band across the plane of the slit the desired spectral region is obtained. Spectrophotometers are usually more expensive than filter photometers, the cost increasing with increased sensitivity, spectral range, and narrowness of the spectral region isolated.

<sup>10</sup> Manufacturers of spectrophotometers include Beckman Instruments, Inc., South Pasadena, Calif.; Coleman Instruments, Inc., Maywood, Ill.; and Central Scientific Co., Chicago. Information may also be obtained from the larger laboratory supply houses.

For routine analytical purposes, particularly in the visible region of the spectrum, spectrophotometers have the advantage over filter photometers of greater convenience and flexibility in choice of wavelength; this is offset to a certain extent by the increased cost as compared to filter photometers of equal or greater accuracy, and by the increased technical skill required in operation and maintenance. The wavelength setting is an extra adjustment connected with each analysis; variation or alteration is obviously more likely to occur than if a stable glass filter of suitable optical characteristics is used for controlling the spectral range. Errors due to inaccurate wavelength setting may be minimized in an analysis if results are obtained in terms of a standard prepared and read under the same conditions as for the unknown, but in any event frequent checking of the accuracy of the wavelength setting is important. The major use of spectrophotometers in photometric analysis at the present time is in connection with substances whose light absorption is in the ultraviolet or infrared regions of the spectrum, since no other type of instrument can be used for this particular purpose, and for the establishment of the complete spectral characteristics of a color (i.e., the absorption spectrum).

The Beckman quartz spectrophotometer is especially adapted to measurements in the ultraviolet and has had wide application in the study of vitamin A, sterols, hormones, etc. An infrared model is also available.

**Choice of Photometers.** The choice of photometers from the many types commercially available is largely a question of the requirements of the individual laboratory. For routine analytical purposes based upon established procedures, any good type of filter photometer will prove satisfactory. Instruments equipped for the use of test tubes as solution containers are preferable to other types, because of the convenience and low cost of this type of cuvette; in some laboratories, however, measurements may have to be made at varying depths of solution, and an instrument capable of being used with different sizes of containers will be required. If a single-photocell type instrument is desired, the stability on the laboratory current should be tested before use, or facilities for maintaining a storage battery must be available. Filter photometers differ considerably in the width of spectral band transmitted by the filters supplied with the instrument; in general, the narrower the band the more satisfactory will be the photometer; agreement with Beer's law cannot be expected with filters transmitting a wide range of wavelengths. For analytical purposes, a spectrophotometer covering only the visible and neighboring portions of the spectrum is little better than a good filter photometer, except for the convenience of wavelength selection. For investigational purposes the spectrophotometer should be usable in the ultraviolet and near infrared regions as well as in the visible region; an ideal combination would include such a spectrophotometer for investigational purposes, and a good filter photometer for analytical purposes.

**Turbidimetry and Nephelometry.** The light transmittance of a fluid is influenced not only by the amount of light-absorbing material present in solution but also by the presence of light-scattering or light-obstructing material such as insoluble substances in suspension. Quantitative analysis of substances in suspension based upon this principle is

known as turbidimetry or, less commonly, nephelometry. These two terms are substantially equivalent, although nephelometry is usually considered to include the use of the intensity of scattered light (i.e., light at right angles to the incident beam) as a measure of turbidity, as well as methods based on transmittance measurements. Of the two principles mentioned (light-scattering and transmittance) the latter is more commonly used.

It is to be noted that in nephelometric determinations it is not the intensity of the light beam itself that is measured but that of the light scattered at right angles (see Fig. 140). Hence for low concentrations this

FIG. 140. KLETT NEPHELOMETER.

The instrument is especially constructed for nephelometric work, providing for parallel light which illuminates the cups at right angles. The cups are made of clear glass tubing with black bottoms.

Courtesy, Klett Manufacturing Co.

method is said to be more sensitive, because a dark background represents zero concentration, whereas there is full illumination at zero concentration in turbidimetric measurements. The chemical principles for producing turbid systems are the same in both turbidimetry and nephelometry and the same precautions must be taken in their preparation and use.

Turbidimetric measurements may be carried out by the same procedure and instruments used for the measurement of substances in solution, i.e., by comparison against a series of standards, by dilution, by varying the depth of solution, or by direct measurement of the light transmittance. Transmittance measurement, particularly when used in instruments equipped with photoelectric cells, is the most sensitive and satisfactory. The relationship between the amount of a substance in suspension and the turbidity or transmittance of the fluid is much more empirical than for substances in solution, depending as it does not only on the amount of

material present but also on the size and shape of the suspended particles, their relative opacity or transparency, the relation between particle size and the wavelength of light used, and the uniformity with which a given turbidity may be reproduced. For a particular procedure, however, it may be found that over a limited range of concentration the turbidity or transmittance is directly proportional to concentration, and thus resembles optical density or extinction for substances in solution. In such an instance, turbidity measurement is carried out and results calculated in the same manner as for light absorption. In other cases, results must be obtained from a calibration curve constructed from known standards; it is even more important here than for substances in solution that the conditions prevailing at the time the standard turbidities were obtained be reproduced as closely as possible in an analysis.

If the substance in suspension is colorless in a colorless solvent, it may appear at first glance that the choice of wavelength or filter for photometric measurement is immaterial. This is not so, because of the influence of particle size on the scattering of light of different wavelengths ("Tyndall effect"). In general, light of shorter wavelength (at the blue end of the spectrum) is relatively more highly scattered than light of longer wavelength (red end of the spectrum), therefore the change in transmittancy for unit change in turbidity will be greater with short wavelengths than with long wavelengths. Thus the sensitivity of the procedure, or the relationship between scale readings and turbidity, may be considerably influenced by the wavelength employed. Other considerations may of course enter into the choice of wavelength; occasionally the interference of extraneous colored material in solution may be minimized by selection of a wavelength which is not absorbed by such material.

Turbidimetric measurements are employed not only for analytical purposes but also for the evaluation of particle size, and for determining the approximate number of plant or animal cells (yeast, bacteria, etc.) present in a fluid; this latter has had wide application, particularly in the field of microbiological assay. Turbidimetric estimation of red blood cell count has not as yet been successfully achieved. The use of turbidimetric methods in analytical chemistry has not been great, largely because of the difficulty of achieving a reproducible turbidity for a given concentration. Use has sometimes been made of a protective colloid to stabilize suspensions and promote uniformity; unfortunately, protective colloids usually distort the relationship between turbidity and concentration in such a way as to require a calibration curve which is highly empirical, and their use cannot be said to have solved the problems of turbidimetric analysis.

**Fluorimetry.** Certain substances are capable of absorbing light at one wavelength and radiating a portion of this absorbed light at some other wavelength. This phenomenon is known as fluorescence and may be used for analytical purposes, the intensity of fluorescence serving as a measure of concentration. Instruments designed for this purpose are known as fluorimeters. The fluorescence of the unknown may be compared visually against a standard or series of standards, or the intensity of the fluorescent light may be measured directly, using a light-sensitive device such as a

photoelectric cell. Fluorimeters utilizing the latter principle are illustrated in Figs. 141—143.

The exciting light is usually in the ultraviolet portion of the spectrum, generally between 300 and 400  $m\mu$ , and the radiated light is usually in the

FIG. 141. FLUOROPHOTOMETER MODEL B.

Courtesy, Pfaltz & Bauer, Inc.

FIG. 142. KLETT FLUORIMETER.

Courtesy, Klett Manufacturing Co.

visible region, but the applications of fluorescence are not limited to these conditions. Since the intensity of fluorescence is determined not only by those factors which affect light absorption (concentration, depth of solution, wavelength) but also by the intensity of the exciting light, measurements must be made at a uniform or controlled incident light intensity,

and the sample viewed or measured from the side of the light beam, to prevent interference from light transmitted through the solution. With photoelectric fluorimeters, results are usually obtained from a calibration curve relating the intensity of fluorescence to known concentrations of the substance; this relationship may be linear over a certain concentration range, in which case results can be obtained by calculation in terms of the fluorescence of a known standard. Permanent fluorescent standards such as uranium glass or solutions of quinine sulfate may also be used to control the calibration. Some substances show a "bleaching" or decrease in fluorescence during exposure to the exciting light; errors from this

FIG. 143. CENCO-FRIEDEMANN-LIEBECK FLUORIMETER.

Courtesy, Central Scientific Co.

source may be minimized by rapid reading (short exposure), extrapolation, or the use of a low intensity of exciting light. Blank determinations to correct for intrinsic fluorescence of containers and reagents may be necessary; specificity may sometimes be enhanced by measuring the change in fluorescence after specific (e.g., enzymatic) destruction of the substance being determined. Quantitative analysis based upon fluorescence is limited at present to the determination of certain vitamins (see Chapter 35), drugs, dyes, and inorganic ions, but its usefulness should increase with further study.

## EXPERIMENTS ON PHOTOMETRY

**1. Characteristics of Photometer.** Examine the photometer available and note the general principles of its design and operation. (This information

may be obtained from the instructor or from the manual usually supplied by the manufacturer of the instrument.) Is it a filter photometer or a spectrophotometer? Note particularly the type of scale used, and whether it is graduated in terms of per cent transmittancy, optical density, or units proportional to optical density. Place some distilled water in a photometer cuvette<sup>11</sup> and insert the cuvette in the instrument. Select any particular filter or wavelength setting, turn on the light, and adjust the photometer to its initial setting, which will represent either zero optical density or 100 per cent transmittancy—which is used? Now remove the cuvette from the light path. Does the adjustment change? Replace the cuvette. Does the reading return to its initial value? If it does not, allow the light to burn for about 5 minutes, reset to zero (or 100) and repeat the test of stability. Is there any increase in stability after the light has been on a short while? Why is it necessary for photometer readings to be based on a constant initial setting?

2. *Beer's Law.* Obtain some defibrinated or oxalated blood. Dilute 1 ml. of this to 100 ml. in a volumetric flask with dilute ammonia solution (4 ml. of concentrated ammonium hydroxide per liter of water). Mix well by inversion. Prepare a series of known dilutions of this "stock standard" as follows: into test tubes place 0.0, 1.0, 2.0, 3.0, etc., up to 10.0 ml. portions of the stock solution, and add sufficient dilute ammonia solution to each tube to make the final volume 10 ml. in each case. Mix. Using light of 520  $m\mu$  wavelength, adjust the photometer to zero optical density (or 100 per cent transmittance) with the contents of the first tube, which is a "reagent blank." Determine the photometer readings for each of the other solutions, checking the initial setting with the blank solution once or twice during the series of readings; if any change has occurred reset the photometer before continuing with the readings.

On a sheet of cross-section paper, plot the photometer readings on the y-axis against equivalent concentration (0, 1, 2, 3, etc., up to 10) on the x-axis, and connect the points by a smooth curve. Which of the four types of curves shown in Fig. 127, p. 517, do you obtain? What is the relation between photometer readings and concentration? If the photometer scale reads in terms of per cent transmittancy, (a) compute the value of  $\log T_s$  for each concentration and plot this value against concentration on a second sheet of cross-section paper (or plot  $T_s$  on the logarithmic axis of semilogarithmic paper, against concentration on the linear axis), and (b) convert transmittancy into optical density by the use of the table on p. 520, and plot optical density against concentration, using ordinary cross-section paper. What types of curves should be obtained if Beer's law is valid? Do your results indicate that hemoglobin solutions obey Beer's law under the conditions you are using? How may your results be used as a basis for the photometric determination of hemoglobin?

Assume that one of your solutions is a standard, of known concentration, and that the others are unknowns. Calculate their concentrations relative to that of the standard, from the determined optical densities, as described on p. 518. Is Beer's law applicable over the entire range of concentration you are

<sup>11</sup> Cuvettes, cells, and test tubes used in photometric instruments must be thoroughly clean and free of scratches. A chromic-sulfuric acid solution may be employed, followed by thorough rinsing with distilled water. Do not use alkaline detergent solutions, because of the danger of etching the polished surfaces. Use a fresh piece of soft lintless paper, such as lens paper or Kleenex, to wipe dry the outside of the vessel before placing it in the instrument. Care should be taken not to let the fingers touch the glass surfaces which will be exposed to the light path. A handkerchief or towel should not be used for wiping cuvettes, etc.

using? What must be done in a photometric analysis if (a) the procedure does not obey Beer's law, or (b) a reading falls outside the range of application of Beer's law?

3. *Relation between Transmittancy and Wavelength.* Repeat Exp. 2, but use a wavelength in (a) the blue portion of the spectrum, and (b) the red portion. Plot the results graphically for each wavelength used, and compare with the results of Exp. 2. How may the wavelength chosen influence the sensitivity of a photometric procedure? What is the indication on your graphs of the sensitivity of this particular procedure? Suppose hemoglobin were a contaminant of a solution, instead of the substance being measured; at what wavelength would its presence cause the least error?

4. *Relation between Transmittancy and Depth of Solution.* Repeat Exp. 2, but make measurements at some other depth of solution, if such facilities are available. If not, compute the theoretical reading for each concentration at a depth of solution twice that used in Exp. 2. Plot the data graphically and compare with the previous results. What is the effect of solution depth on the transmittancy value for a given concentration? How may this be used to increase the sensitivity of a photometric procedure?

5. *Correcting for a Blank Color.* Set up the aliquots of 1:100 hemoglobin stock solution used in Exp. 2 (up to 9 ml.) but before diluting to 10 ml. with dilute ammonia solution, add to each tube 0.5 ml. of a dilute ammonia solution to which a few drops of blood have been added, sufficient to give a noticeable pink color. Thus each solution now contains a relatively known amount of hemoglobin, plus a constant blank color. Adjust the photometer to its initial setting with the blank tube, and read the other solutions relative to this, as before. Plot the data as described for Exp. 2. Does the presence of a constant blank color influence the photometric calibration, if the photometer is set to its initial reading with the blank solution? Since optical density is additive—i.e., the total optical density of a solution is the sum of the densities due to the various light-absorbing substances present—what other way can you suggest of correcting for the density of a blank?

6. *Effect of Time of Standing on Transmittancy.* Obtain some defibrinated blood, and dilute 0.1 ml. to 25 ml. with 0.1 N hydrochloric acid. Mix by inversion, transfer a portion to a photometer cuvette, and read immediately, the photometer having been previously set to zero optical density at 520 m $\mu$  with the dilute acid alone. Repeat the reading on this same sample at suitable time intervals, say every five minutes, for one hour or until the reading becomes constant. Be sure to check the initial setting of the photometer before each reading. Plot the relationship between time of standing and photometer reading. Many of the colors produced in common photometric procedures show a similar behavior with respect to time of standing. What does this experiment show concerning the desirability of time control in photometric analysis?

7. *Calibration of Test Tubes Used as Cuvettes.* Many types of photometers are designed to use interchangeable test tubes of uniform dimensions as solution containers or cuvettes. If the tubes are truly interchangeable, they should all give the same reading for a given colored solution, and they may be tested on this basis. Prepare a stable colored solution of such intensity that it shows by trial a reading about in the middle of the photometer scale.

A dilute solution of hemoglobin, as described in previous experiments, may be used; an equally satisfactory test solution may be made by diluting ordinary India ink with water to a suitable intensity. Place portions of this test solution in each of the test tubes, and read them in the photometer, using water for the initial setting and checking this setting at suitable intervals. Select all those tubes which give identical or nearly identical readings, and discard the remainder. Sometimes two lots of tubes may be obtained, the readings for each lot centering with the desired accuracy around a particular reading, but a different reading in each case. Each lot may then be used independently, but they should be marked so that the lots will not be mixed. It is also well to mark the tubes so that they will always be placed in the photometer in the same position. Test tubes calibrated in this way are as accurate for photometric purposes as rectangular cuvettes, and much more convenient. A tube should be discarded when it becomes scratched, or when checking shows it to have lost its interchangeability.

## GENERAL PROCEDURES IN BLOOD ANALYSIS

**Drawing Blood for Analysis.** Except when analytical methods permit the use of a few drops of blood (drawn from the finger tip, toe, or ear lobe), samples of blood are usually obtained by venipuncture.

*Procedure.* Draw a tourniquet (of soft, firm rubber tubing or a strip of bandage) tightly about the arm of the patient a couple of inches above the elbow. Have the patient clench his fist firmly. Wash the skin surface about the most prominent vein on the inner surface of the elbow (usually the median basilic) with 70 per cent alcohol, allow to dry, hold the vein immobile with the thumb, and into the vein insert a sharp, sterile hypodermic needle (No. 18, an inch and a half long) which is attached to a dry sterile syringe of suitable capacity. The needle should penetrate the vein from the side and at an angle of about  $50^\circ$  with the surface of the arm, the bevel or opening of the needle being kept upward or to the side. As soon as blood is seen to enter the syringe, retract the plunger slowly until the desired amount of blood has entered the syringe. Before removing the needle from the vein, loosen the tourniquet, have the patient unclench his fist, and on the skin at the point of entrance of the needle hold in place a small pad of folded gauze moistened with 70 per cent alcohol. Withdraw the needle, detach it from the syringe, and into a suitable container eject the blood from the syringe (not too vigorously, which might cause hemolysis). Pressure on the gauze pad for a few minutes will effectively prevent bleeding from the skin puncture.

The use of a syringe is not essential; the needle alone may be used. The blood is allowed to flow from the free end of the needle into a suitable container until the desired amount has been obtained. The needle is then withdrawn as described above. For special precautions to be used in drawing blood where the maintenance of physiological gas tensions is important, as in the determination of carbon dioxide content, etc., see Chapter 24.

**Preparation of Whole Blood and of Plasma.** When whole blood or plasma is desired for analysis, the blood must be treated with anti-coagulant before clotting commences. The most convenient way to do this is to have containers for the blood already prepared with sufficient anti-coagulant in the form of a thin dried film over the inside surface (see be-

low). The thin film promotes quick solubility and mixing with the added blood. Test tubes or small wide-mouth bottles of approximately 1-ounce capacity may be used as containers.

**Procedure.** Transfer the blood, as quickly as possible after drawing, from the syringe to a container which has sufficient anticoagulant in the form of a thin dried film to prevent clotting of the blood. Mix by rotation gently but thoroughly to dissolve and distribute the anticoagulant. The blood is now ready for use. To obtain plasma, centrifuge and remove the supernatant plasma with a rubber-bulb pipet.

Blood specimens are best taken in the morning before breakfast, to minimize the influence of food ingestion. Analyses are preferably made as soon as possible after the blood is drawn; during any interval between drawing and analysis, the blood should be kept cold and well stoppered to minimize evaporation. For blood sugar analyses in particular, the protein-free filtrate should be prepared as soon as possible, to minimize loss of sugar by glycolysis.<sup>12</sup> Protein-free filtrates will keep better than whole blood or plasma, particularly if kept cold and in the presence of a drop of toluene as preservative.

**Anticoagulants.** The most commonly used anticoagulant is neutral potassium oxalate, of which from 1 to 2 mg. are required per ml. of blood. Only an amount of anticoagulant sufficient for the quantity of blood to be received should be employed; excessive amounts of anticoagulant may interfere with some analyses, cause hemolysis, or produce an abnormal distribution of water and electrolytes between cells and plasma.

**Procedure.** To prepare containers with sufficient potassium oxalate for 6 to 10 ml. of blood, prepare a stock solution of 10 per cent neutral potassium oxalate and pipet 0.1 ml. of this into each container. Rotate to produce maximal spreading; then place in an incubator (or oven at 100° C.) to dry. The oxalate should form a thin dry film on the sides of the container. For smaller quantities of blood, use half as much stock solution. It is good practice to have two sets of containers, suitably labeled, one for 3 to 5 ml. of blood, and one for 6 to 10 ml. of blood.

Other anticoagulants, and the amounts required per ml. of blood, include sodium citrate (5 mg.), lithium or sodium oxalate (1 to 2 mg.), sodium fluoride (10 mg.), and heparin (0.2 mg.). Containers may be prepared with the proper amounts of these anticoagulants in a manner similar to that described above for potassium oxalate. Of the various anticoagulants, heparin is by far the most satisfactory and should be more widely used. Sodium fluoride acts as a preservative<sup>13</sup> and has the advan-

---

<sup>12</sup> Denis (*J. Biol. Chem.*, **44**, 203 (1920)) has shown that for the Folin-Wu sugar method, blood may be preserved for four days or more at room temperatures if 1 drop of commercial formalin (40 per cent) solution is added to each 5 ml. of blood.

<sup>13</sup> John (*Arch. Path. Lab. Med.*, **1**, 227 (1926)) after an extensive study of blood preservatives, recommends sodium fluoride and thymol in the proportion of 20:1, using 20 mg. of the mixture per 10 ml. of blood. Roe, Irish, and Boyd (*J. Biol. Chem.*, **75**, 685 (1927)) find 10 mg. NaF per ml. blood preserves for 10 days as far as nonprotein nitrogen, uric acid, creatinine, sugar, and cholesterol are concerned, provided the blood is sterile. If not, at least 20 mg. are

tage of inhibiting glycolytic decomposition of blood sugar, but interferes with certain methods. A special mixture (Heller and Paul)<sup>14</sup> of ammonium oxalate (3 parts) and potassium oxalate (2 parts) has the advantage of causing no change in red cell volume, and hence is useful for hematocrit determinations and for methods involving the measurement of specific gravity of whole blood or plasma. It cannot be used in ordinary blood analytical procedures because of the presence of ammonia.

**Preparation of Blood Serum for Analysis.** In the collection of blood for serum, care must be taken to avoid trauma and hemolysis.

**Procedure.** When serum rather than whole blood or plasma is desired for analysis, place the freshly drawn blood directly into a small test tube without anticoagulant. Allow to clot at room temperature and then chill thoroughly in the refrigerator. Centrifuge down the clot and remove the supernatant serum with a rubber-bulb pipet.

If a centrifuge is not available, the blood may be allowed to clot with the tube in a slanting position; then after chilling overnight in an upright position the serum may be poured off from the side of the tube opposite the slanting clot.

**Measurement of Blood.** Because of its physical characteristics and the presence of suspended red cells, whole blood is much more difficult to measure exactly than ordinary fluids. Serious errors have been traced to faulty measurement of blood. Before measurement, the sample must be thoroughly mixed to ensure uniform distribution of cells and plasma.

**Procedure.** To mix whole blood without trapping air bubbles, if the sample is in a test tube use a small footed stirring rod which is raised and lowered in the sample a sufficient number of times to ensure complete mixing. If the sample is in a wide flat bottle, place the bottle firmly on the table top and vigorously trace a 1-foot circle with the bottle flat against the table top, for at least a dozen times or until the blood is uniformly mixed. Measure out the portion of blood immediately after mixing, and repeat the mixing procedure before each new measurement.

To measure blood accurately, draw the blood up into a transfer pipet until the level is a little above the graduation mark. Wipe off excess blood from the pipet tip, allow to drain slowly until the blood level is exactly at the mark, and again wipe off excess blood. Deliver the blood into the receiver slowly, adjusting the rate of delivery by finger pressure on the mouthpiece of the pipet so that as the blood drains from the pipet, the pipet walls remain clear

FIG. 144. OSTWALD-FOLIN PIPET.

required, but even this gives poorer results than are obtained with sterile blood. Interference of NaF with urease action is overcome by dilution with 7 to 10 volumes of water if not over 30 mg. of NaF per ml. are used.

<sup>14</sup> Heller and Paul: *J. Lab. Clin. Med.*, 19, 777 (1934).

and there is no visible film of blood remaining behind. When the blood has drained completely, blow out the last drop into the receiver.<sup>15</sup>

Ordinary pipets may be used for blood measurement, with slight error due to the fact that they are usually calibrated for the delivery of water rather than blood. Pipets calibrated "to contain" ("TC"), such as are commonly used in microanalyses, are not subject to this error, since they are designed for delivery of the blood into a second fluid, the resulting mixture then being used to rinse out any blood remaining in the pipet. Folin proposed the use of the Ostwald type pipet (Fig. 144), which has less surface per unit volume than the ordinary pipet, and no sharp shoulders to impede drainage, and these have found favor in many laboratories. Where the amount of blood available is limited and it is desired to use as much as possible, a pipet graduated to the tip is useful (Fig. 145). In using this type of pipet, the greatest error is at the tip, particularly when the tip is imperfect, and if possible the measurement should exclude this portion (i.e., for a 5-ml. portion, measure from the 6-ml. mark to the 1-ml. mark). In general, the most accurate method of measurement is by careful drainage between two accurately established graduation marks. Volumetric pipets constructed on this principle are not generally available; ordinary graduated pipets should be used in this manner whenever possible.

FIG. 145. DILUTING PIPET.

*J. Biol. Chem.*, 38, 81 (1919).

## PREPARATION OF THE PROTEIN-FREE BLOOD FILTRATE

**Method of Folin and Wu.<sup>16</sup> Principle.** The proteins of whole blood, plasma, or serum are removed by precipitation with tungstic acid (formed by the interaction of sodium tungstate and sulfuric acid) and filtration. The filtrate is suitable for the determination of the following: nonprotein nitrogen, urea, uric acid, creatine and creatinine, sugar, amino acids, and chlorides. Sufficient filtrate for one or two determinations is provided by 2 ml. of blood; for all the determinations, about 10 ml. of blood are needed.

**Procedure.<sup>17</sup>** Transfer a measured quantity of blood to a flask having a capacity at least 15 times that of the volume taken. For each volume ( $A$  ml.) of blood taken, add from a buret exactly 7 volumes ( $7 \times A$  ml.) of water and

<sup>15</sup> This is for transfer pipets which are calibrated for blowout delivery. Such pipets are commonly marked by the manufacturer with an etched ring around the pipet near or at the top. If the pipet is calibrated for drainage delivery, allow to drain for 1 minute with the tip of the pipet touching the wall of the receiver. For graduated pipets, allow the blood to run out either to the desired graduation mark, or to the tip if the pipet is graduated to the tip.

<sup>16</sup> Folin and Wu: *J. Biol. Chem.*, 38, 81 (1919).

<sup>17</sup> Reagents Required: *Sodium tungstate, 10 Per Cent Solution.* Dissolve 100 g. of reagent-

mix. Add 1 volume (A ml.) of 10 per cent sodium tungstate solution, and mix. Finally add slowly and with shaking 1 volume (A ml.) of two-thirds normal sulfuric acid. Stopper the flask and shake it. Only a few bubbles should form as a result of this shaking if all the proteins have been precipitated. Let stand for 10 minutes. The color of the mixture should change from red to dark brown. If this change in color does not occur, the coagulation is incomplete, usually because too much oxalate is present. In such an emergency the sample may be saved by adding 10 per cent sulfuric acid, drop by drop with shaking, until there is no foaming and until the dark brown color has set in.

Pour the mixture on a dry folded filter large enough to hold it all. Cover the funnel with a watch glass to minimize evaporation. Collect the filtrate in a clean dry container. If the first few drops of filtrate are not absolutely clear, return this portion to the funnel and replace the receiver with a fresh one. Allow to filter until as much filtrate as possible has been obtained.

For plasma or serum the procedure is similar except that 8 volumes of water and only  $\frac{1}{2}$  volume of both tungstate and acid are used.

The following modifications of the Folin-Wu precipitation employ fewer solutions and yield more filtrate.

**Haden's<sup>18</sup> Modification.** Add directly to the blood from a buret, 8 volumes of N/12 sulfuric acid.<sup>19</sup> Laking and darkening occur rapidly. Add 1 volume of 10 per cent sodium tungstate, shake well, and filter, as above.

**Van Slyke and Hawkins'<sup>20</sup> Modification.** Add directly to the blood, 9 volumes of a mixture of 8 parts N/12 sulfuric acid and one part 10 per cent sodium tungstate. Shake and filter, as above. The precipitating solution should be clear and not more than two weeks old.

Blood filtrates prepared by any of the above methods represent a 1:10 dilution of the sample; that is, 1 ml. of filtrate corresponds to 0.1 ml. of original material. Since any error in measurement of the added reagents will produce a corresponding error in calculations, which are based upon the assumption of an exact 1:10 dilution, all measurements must be made carefully, preferably by the use of calibrated pipets or burets.

The protein-free filtrates are not acid enough to prevent bacterial decomposition. If the filtrates are to be kept more than about 12 hours a few drops of toluene or xylene should be added. For optimum precipitation of protein, the filtrate should not be more alkaline than pH 2.8.<sup>21</sup> A

---

grade, carbonate-free sodium tungstate ( $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$ ) in water and dilute to 1 liter. Stable indefinitely.

**Two-thirds Normal Sulfuric Acid.** Weigh out 35 g. of concentrated sulfuric acid in a small tared beaker, dilute to 1 liter with water, and mix. Check by titration against standard alkali and adjust if necessary. The two-thirds normal acid is intended to be equivalent to the sodium tungstate, so that when equal volumes are mixed substantially the whole of the tungstic acid is set free without the presence of an excess of sulfuric acid. The liberated tungstic acid is taken up almost quantitatively by the blood proteins, to yield a filtrate which is only slightly acid.

<sup>18</sup> Haden: *J. Biol. Chem.*, **56**, 469 (1923).

<sup>19</sup> Equivalent to combining 1 volume of  $\frac{2}{3}$  N acid with 7 volumes of water. Add 2.5 ml. of concentrated sulfuric acid to 1 liter of distilled water. Mix well and check by titration against 0.1 N NaOH. 20 ml. of N/12 acid should require 16.7 ml. of 0.1 N NaOH for its neutralization.

<sup>20</sup> Van Slyke and Hawkins: *J. Biol. Chem.*, **79**, 739 (1928).

<sup>21</sup> Merrill: *J. Biol. Chem.*, **60**, 257 (1924).

drop of 0.04 per cent bromophenol blue added to a few drops of filtrate on a test plate should give a yellow or greenish-yellow color, alkalinity being denoted by a pure blue shade.

**Other Methods of Deproteinization.** Although tungstic acid filtrates prepared as described above are the most satisfactory for general purposes, many other reagents have been used for the deproteinization of blood and other biological fluids. Examples of the use of certain of these (zinc and copper hydroxides, trichloroacetic acid, etc.) will be found subsequently in this chapter. In most cases they are employed in particular analytical techniques in which tungstic acid filtrates have been found unsatisfactory for one reason or another. Hiller and Van Slyke<sup>22</sup> have reported on the comparative value of a number of common protein precipitants. Benedict and Newton<sup>23</sup> recommend the use of tungstomolybdic acid in place of tungstic acid for the preparation of blood filtrates, not only for general purposes but also specifically for the determination of blood ergothioneine, for which tungstic acid filtrates are unsatisfactory.

## DETERMINATION OF NONPROTEIN NITROGEN

**Introduction.** The nonprotein nitrogen (NPN) of the blood is a collective concept and includes the nitrogen from all of the nonprotein nitrogenous constituents of blood which are found in a protein-free filtrate, such as urea, uric acid, creatine and creatinine, amino acids, glutathione, and many others in small amount, some of which are of unknown nature. Of these various substances, the compound urea contributes by far the largest share to the total, urea nitrogen representing ordinarily about 45 per cent of the blood NPN. The nonprotein nitrogen content of blood is usually determined by various micro modifications of the standard Kjeldahl method for the determination of total nitrogen (see Chapter 31).

**1. Method of Folin and Wu:<sup>24</sup> Principle.** Nitrogen is determined in a portion of the protein-free blood filtrate by a micro-Kjeldahl method, using a sulfuric and phosphoric acid mixture for the digestion, the ammonia formed being determined colorimetrically after direct nesslerization of the digestion mixture.

**Procedure.<sup>25</sup>** Transfer 5 ml. of blood filtrate to a large test tube (pyrex) 200 mm. × 25 mm., graduated at 35 ml. and 50 ml. The test tube should either be dry or rinsed with alcohol to reduce the danger of bumping. Add 1 ml. of diluted acid mixture and a quartz pebble. Boil vigorously over a

<sup>22</sup> Hiller and Van Slyke: *J. Biol. Chem.*, 53, 253 (1922).

<sup>23</sup> Benedict and Newton: *J. Biol. Chem.*, 83, 357 (1929).

<sup>24</sup> Folin and Wu: *J. Biol. Chem.*, 38, 81 (1919). For a gasometric method, see Van Slyke: *J. Biol. Chem.*, 71, 235 (1927).

<sup>25</sup> Reagents Required: *Diluted Acid Mixture*. Made by diluting "regular acid mixture" with an equal volume of water. To prepare "regular acid mixture," add 300 ml. of 85 per cent phosphoric acid, reagent grade, to 50 ml. of a 5 per cent copper sulfate solution. Add 100 ml. of reagent-grade concentrated sulfuric acid and mix. Keep well stoppered to prevent absorption of ammonia from the air.

*Nessler's Solution*. See Appendix.

*Standard Ammonium Sulfate Solution*. Dissolve exactly 0.236 g. of reagent-grade ammonium sulfate in water, transfer quantitatively to a 1-liter volumetric flask with rinsings, add a few drops of concentrated sulfuric acid, make up to volume with water, and mix. This

microburner until the characteristic dense fumes begin to fill the tube. This will happen in from 3 to 7 minutes, depending on the size of the flame. When the test tube is nearly full of fumes reduce the flame sharply so that the speed of the boiling is reduced almost to the vanishing point. Cover the mouth of the test tube with a watch glass. Continue the gentle heating for 2 minutes, counting from the time the test tube became filled with fumes. If the oxidation is not visibly finished at the end of 2 minutes the heating must be continued until the solution is nearly colorless. At the end of 2 minutes remove the flame and allow the digestion mixture to cool for 70 to 90 seconds. Then add 15 to 25 ml. of water. Cool further approximately to room temperature and then fill with water to about 1 cm. under the 35-ml. mark. Set aside until the standard is ready, since in this determination it is important that color development be carried out in both unknown and standard under as nearly identical conditions as possible.

A standard suitable for either colorimetric or photometric measurement is prepared as follows: transfer 3 ml. of a standard solution of ammonium sulfate, containing 0.15 mg. of nitrogen, to a graduated tube similar to that used for the blood filtrate, add 1 ml. of the diluted phosphoric-sulfuric acid mixture, to balance the acidity of the unknown, and dilute with water to about 1 cm. under the 35-ml. mark. For photometric measurement a third or blank tube is required, containing 1 ml. of diluted acid mixture alone, made up with water as described for unknown and standard.

When all the tubes are ready, nesslerize each individually as follows: measure out 15 ml. of Nessler's solution in a graduated cylinder, set the tube contents in motion by gentle rotatory shaking, and in one continuous motion pour the Nessler solution into the tube. Do not wait for the Nessler solution to drain completely from the cylinder, since the exact amount of Nessler solution is relatively unimportant, but immediately add water to the tube contents up to the 50-ml. mark, insert a clean rubber stopper, and mix by inversion. Proceed immediately to the nesslerization of the remaining solutions in a similar manner. Allow the solutions to stand 10 minutes after adding the Nessler reagent and mixing, to permit maximum color development, and read within the next 10 minutes or so. Prolonged standing may lead to the development of a turbidity which renders the color comparison difficult or even worthless.<sup>26</sup> Occasionally a turbidity is present before nesslerization, due to the action of the acid digestion mixture on the glass of the tube. This turbidity can be removed by centrifuging a portion of the colored solution before color comparison.

For colorimetric measurement, match the standard against itself at 20 mm. in the usual way, and then compare the unknowns against the standard. For photometric measurement, transfer portions of the colored solutions to suitable containers and determine the densities in the pho-

---

solution is stable indefinitely and contains 0.05 mg. of nitrogen per ml. Dry the ammonium sulfate before weighing it out by heating in an oven overnight at 100° C.

In all nitrogen analyses involving the determination of small amounts of ammonia, only the highest purity ammonia-free reagents may be used, and solutions must be kept protected to prevent the absorption of ammonia from the air. Distilled water containing ammonia cannot be used; to free it from ammonia, redistil in the presence of a little sulfuric acid in an all-glass still, and protect the distillate from exposure to ordinary laboratory air by a trap containing dilute sulfuric acid.

<sup>26</sup> Chilling all solutions in cold water for 10 minutes prior to adding the Nessler reagent has been recommended to prevent the formation of turbidity before reading, as has also the addition of a few drops of 2 per cent gum ghatti solution (see Appendix) to standard and unknowns just before nesslerization. The use of gum ghatti solution is not recommended unless absolutely necessary; for further discussion, see footnote 35, p. 551.

tometer at 480 to 540  $m\mu$  (see below), setting the photometer to zero density (100 per cent transmittance) with the blank.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.15 \times \frac{100}{0.5} = \text{mg. of NPN per 100 ml. of blood}$$

The standard indicated is satisfactory for the range of 15 to 60 mg. per cent blood NPN. For amounts outside this range, repeat the analysis using less or more filtrate as necessary, and correct the calculations accordingly.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.15 \times \frac{100}{0.5} = \text{mg. of NPN per 100 ml. of blood}$$

The spectrophotometric characteristics of the Nessler reaction with ammonia are illustrated in Fig. 240, p. 879. For the amounts of nitrogen which are concerned here, satisfactory agreement with Beer's law is found with any filter or wavelength setting between 480 and 540  $m\mu$ , the choice depending largely upon the sensitivity desired. In a 1-cm. cuvette, at 480  $m\mu$ , the density of the standard prepared as described above is approximately 0.250. This means that up to about 120 mg. per cent blood non-protein nitrogen may be accurately determined under these conditions. For higher values, or with deeper cuvettes, where the range is proportionately reduced, use less filtrate for the analysis and correct the calculations accordingly.

**Interpretation.**<sup>27</sup> The nonprotein nitrogen content of normal blood ranges from 25 to 35 mg. per 100 ml. Variations in blood NPN content are ordinarily due largely to variations in urea content. Increased values for nonprotein nitrogen are observed in nephritis, more especially in the chronic types and in terminal stages, where they may have prognostic significance, although uremic symptoms may develop without marked elevation of nonprotein nitrogen. The direction of change will impart greater information than the magnitude of an isolated determination.

In regard to the choice of determining either the nonprotein or the urea N as a clinical test of renal function, the advantages seem to be in favor of the latter, for the following reasons: urea covers a relatively wider range of variation in disease; it is a single chemical compound rather than a mixture of partly undetermined composition; it is simple to determine clinically, especially if direct nesslerization of the Folin-Wu filtrate is employed. It is of interest, however, that the urea fraction of the non-protein nitrogen, which usually rises in renal disease, shows subnormal values in cases of eclampsia, suggesting an increase in the "rest N" fraction which may contain toxic split-products of protein metabolism.

**2. Method of Koch and McMeekin:**<sup>28</sup> **Principle.** This method differs from the preceding one in that sulfuric acid and hydrogen peroxide are used in the digestion.

<sup>27</sup> For review, see Folin: *Physiol. Revs.*, 2, 460 (1922); also Peters and Van Slyke's book (see Bibliography at end of chapter).

<sup>28</sup> Koch and McMeekin: *J. Am. Chem. Soc.*, 46, 2066 (1924). A stronger acid digestion mixture containing perchloric acid is used by Rose: *J. Biol. Chem.*, 64, 253 (1924). A saturated solution of  $\text{NH}_3$ -free potassium persulfate is recommended by Wong: *J. Biol. Chem.*, 55, 431 (1923). There is some evidence that both hydrogen peroxide and perchloric acid may yield inconstant results, possibly through oxidation of a portion of the ammonia, although the procedures appear to be sufficiently reliable for routine clinical purposes. Selenium is said to be satisfactory as an oxidation catalyst, and appears to give good results (see Campbell and Hanna: *J. Biol. Chem.*, 119, 1 (1937)).

**Procedure.**<sup>29</sup> Transfer 5 ml. of the 1:10 protein-free filtrate to a 200 × 25 mm. pyrex test tube, add 1 ml. of 1:1 sulfuric acid and a small quartz pebble, and heat over a microburner to evaporate off the water. When charring begins and white fumes begin to appear in the tube, reduce the size of the flame or raise the tube so that the tip of the flame just touches the bottom of the tube. Continue heating until no further darkening occurs. Remove the flame, allow the tube contents to cool for about 1 minute, and then add 1 drop of 30 per cent hydrogen peroxide, allowing it to drop directly into the solution. Replace the flame and heat again to boiling. If the solution is not decolorized repeat the addition of the hydrogen peroxide. Finally boil gently for 5 minutes. Cool, transfer to a 50-ml. volumetric flask with about 35 ml. of water, and set aside until the standard is ready. Test tubes graduated at 35 and 50 ml. as described for the previous procedure may be used here instead of volumetric flasks. To prepare the standard, transfer 3 ml. of standard ammonium sulfate solution, containing 0.15 mg. of nitrogen, to a 50-ml. volumetric flask, add 1 ml. of 1:1 sulfuric acid, and dilute to about 35 ml. with water. For photometric measurement a blank is prepared in a third flask by diluting 1 ml. of 1:1 sulfuric acid to about 35 ml. with water.

When ready, to each flask add 12 ml. of modified Nessler reagent from a graduated cylinder, swirling the contents of the flask just before adding the Nessler reagent to promote quick and uniform mixing. Dilute immediately with water to the 50-ml. mark, stopper, and mix by inversion. Allow to stand 10 minutes before reading. Read in the colorimeter or photometer exactly as described for the previous method, using the same calculations.

**Interpretation.** See previous method.

**Other Methods.** As has been indicated, most of the modifications in the micro-Kjeldahl determination of blood nonprotein nitrogen by direct nesslerization involve changes in the digestion mixture. Alternate procedures for the determination of the ammonia formed include gasometric estimation (Van Slyke, *loc. cit.*); aeration of the ammonia from the alkalinized digest as described for the determination of urea (see next section); or steam distillation of the ammonia (see Chapter 31). In both aeration and steam distillation, the recovered ammonia is absorbed in acid and may be estimated by titration or by nesslerization; the advantage of nesslerization after separation of the ammonia from interfering material is that crystal-clear colored solutions are invariably obtained. A steam distillation device such as that illustrated in Fig. 241, p. 881, or its equivalent, is convenient, almost automatic in operation, and requires but a few minutes for each sample. Steam distillation prior to estimation of ammonia is recommended for all precise micro-Kjeldahl analyses. For very small amounts of nitrogen (ammonia), the microdiffusion method of Conway (see pp. 668 and 886) has given excellent results.

---

<sup>29</sup> Reagents Required: *Sulfuric Acid*, 1:1. With stirring, carefully add 50 ml. of concentrated sulfuric acid to 50 ml. of water. Cool and keep well stoppered to prevent absorption of ammonia from the air.

*30 Per Cent Hydrogen Peroxide.* Only the highest grade, low-nitrogen reagent (Merck's or Baker's are satisfactory) may be used. This reagent is extremely corrosive to the skin and must be dispensed with care, preferably by the use of a rubber-bulb pipet. Keep in the refrigerator when not in use.

*Modified Nessler Solution.* See Appendix.

*Standard Ammonium Sulfate Solution.* See previous method.

## DETERMINATION OF UREA

**Introduction.** Practically all of the methods in use at the present time for the determination of the urea content of blood are based upon incubation with preparations of the enzyme urease,<sup>30</sup> whereby urea present is converted into ammonium carbonate. The ammonia formed may then be determined directly by colorimetric methods, or separated by either aeration or distillation and then determined either colorimetrically or titrimetrically. The carbon dioxide produced by decomposition of ammonium carbonate may also be measured gasometrically.<sup>31</sup> Several methods which do not involve the use of urease have also been described.<sup>32</sup> The choice of procedure among the many available appears to be largely a question of the facilities and requirements of the individual laboratory.

**1. Method of Folin and Svedberg:<sup>33</sup> Principle.** The ammonia produced by the action of urease on the protein-free blood filtrate is distilled off and determined colorimetrically by reaction with Nessler's reagent. For a discussion of the accuracy of this method see Gentzkow (*J. Biol. Chem.*, **143**, 540 (1942)).

**Procedure.<sup>34</sup>** Transfer 5 ml. of tungstic acid blood filtrate to a pyrex test tube of 30 ml. capacity (tubes which previously contained Nessler solution should be rinsed with concentrated nitric acid and then with water before use).

<sup>30</sup> Marshall: *J. Biol. Chem.*, **15**, 487 (1913).

<sup>31</sup> Van Slyke: *J. Biol. Chem.*, **73**, 695 (1927).

<sup>32</sup> Ormsby: *J. Biol. Chem.*, **146**, 595 (1942); Barker: *ibid.*, **152**, 453 (1944); Archibald: *ibid.*, **157**, 507 (1945). See also method of Leiboff and Kahn (p. 555).

<sup>33</sup> Folin and Svedberg: *J. Biol. Chem.*, **88**, 77 (1930).

<sup>34</sup> Reagents Required: *Acetate Buffer Solution*. Dissolve 15 g. of crystallized sodium acetate in a 100 ml. volumetric flask by the help of 50 to 75 ml. of water. Add 1 ml. of glacial acetic acid, dilute to volume, and mix.

*Urease Solution*. Transfer 0.5 g. of jack bean meal to a clean 50-ml. flask; add 20 ml. of 30 per cent (by volume) alcohol. Shake for 10 minutes and filter or centrifuge. This extract should always be prepared on the day it is to be used, because on standing even in an icebox it will develop ammonia and will yield too high results. One should therefore not use more extract or a stronger extract than is really necessary. Koch (*J. Lab. Clin. Med.*, **11**, 776 (1926)) obtains a stable and active urease preparation by making a 75 per cent glycerol extract of jack bean meal.

*Urease Paper*. Transfer to a clean 200-ml. flask 30 g. of jack bean meal and 100 ml. of dilute alcohol (30 ml. of 95 per cent alcohol diluted to 100 ml.). Add 1 ml. of the buffer mixture described above. Stopper tightly and shake vigorously for at least five minutes and then shake less hard for about 10 minutes. Filter, or preferably centrifuge half an hour in 15-ml. tubes, the mouths of which have been covered with tinfoil. Transfer the extract to a porcelain dish and at once take it up on strips of rather heavy filter paper, Schleicher and Schüll, No. 597, and hang these up to dry over two threads about 15 cm. apart. While drying, the papers should not be exposed to air currents, for blasts of air seem to destroy the enzyme so long as water is present. As soon as the paper strips are thoroughly dry, cut them up into pieces about 1 cm. by 2.5 cm. and preserve in wide-mouth bottles. These urease papers will retain their activity for many months and even for years. The urease becomes fixed in the paper and it is only by shaking the solution several times during the digestion that one secures adequate contact and quantitative hydrolysis of the urea.

*Antibumping Tube*. As illustrated in Fig. 146. Made preferably from pyrex glass, 2 mm. in diameter at open end. May be obtained from Fisher Scientific Co., New York.

*Antifoaming Oil Mixture*. To one volume of crude fuel oil add about 10 volumes of toluene.

*Saturated Borax Solution*. Dissolve about 40 g. of reagent-grade sodium tetraborate (borax) in 1 liter of boiling water and allow to cool to room temperature. If unsaturated, add more borax and again heat.

*0.1 N Acid*. Either hydrochloric or sulfuric may be used, and it need not be standardized.

*Standard Ammonium Sulfate Solution*. Prepare a stock standard solution as follows: Dis-

Add 2 drops of acetate buffer solution and either 1 ml. of urease solution (prepared the same day) or a piece of urease paper. Insert a cork and then either let stand at room temperature for 25 minutes or immerse for 10 minutes in 700 ml. of water, having an initial temperature of about 45° C. Longer digestion does no harm. If urease paper is used the tube must be shaken occasionally during the digestion period. Cool the tube if warm and add an antibumping tube, 2 drops of antifoaming oil mixture, and 2 ml. of saturated borax solution. Connect at once with the delivery tube and a test tube receiver

FIG. 146. MICRODISTILLATION APPARATUS FOR UREA DETERMINATION.

Note antibumping tube inside Tube A (Folin and Svedberg).

graduated at 25 ml. as shown in Fig. 146. The receiver contains 1 ml. of 0.1 N acid and 1 ml. of water. Fasten the boiling tube in a clamp and start the distillation by applying the flame of a microburner, preferably surrounded by a shield to prevent fluctuation of the flame due to air currents. As soon as the contents are nearly boiling, reduce the flame partially so that the first minute of boiling is very gentle. Then boil briskly for about three minutes and finally another minute with the delivery tube slightly raised from the surface of

---

solve 0.944 g. of dry reagent-grade ammonium sulfate in water, transfer with rinsings to a 1 liter volumetric flask, add a few drops of concentrated sulfuric acid, dilute to volume with water, and mix. This solution contains 1 mg. of nitrogen in 5 ml. and is stable indefinitely. To prepare the dilute standard used in the procedure, dilute 5 ml. of stock standard to 100 ml. with water. This solution contains 0.1 mg. of nitrogen in 10 ml., and is prepared fresh daily.

liquid in the receiver. To another test tube like the receiver, transfer 10 ml. of standard ammonium sulfate solution (containing 0.1 mg. of N), and 1 ml. of 0.1 N acid. Dilute both to a volume of about 20 ml.,<sup>35</sup> add 2.5 ml. of Nessler solution, dilute to the mark, mix and make the color comparison, using either a colorimeter or a photometer. For photometric measurement, prepare a blank tube containing 1 ml. of 0.1 N acid, water to about 20 ml., add 2.5 ml. of Nessler solution, dilute to 25 ml. and mix. Set the photometer to zero density with the blank, and determine the densities of standard and unknowns as described for the determination of nonprotein nitrogen on p. 547.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.1 \times \frac{100}{0.5} = \text{mg. urea N per 100 ml. blood}$$

The standard is satisfactory for blood values between 8 and 40 mg. per cent. For higher values, repeat the determination with less filtrate plus water.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.1 \times \frac{100}{0.5} = \text{mg. urea N per 100 ml. blood}$$

Under the photometric conditions specified on p. 547, the standard has a density of roughly 0.300. Up to 60 mg. per cent blood urea N may be measured satisfactorily. For higher values, or with cuvettes of greater depth than 1 cm., the analysis is carried out on less filtrate plus water, and the calculations corrected accordingly.

For separation of ammonia by aeration rather than distillation, see the next procedure.

**Interpretation.** Normally, the urea nitrogen of whole blood varies between 10 and 15 mg. per 100 ml. On a restricted hospital diet, however, values below 20 mg. should not be regarded as abnormal. In early nephritis the urea nitrogen may rise to 30 or 40 mg., but in the terminal stages of chronic nephritis and in some cases of acute nephritis marked urea retention may occur. High values may also be found in other conditions associated with damaged renal function, such as mercury bichloride poisoning, double polycystic kidney, intestinal obstruction, prostatic obstruction (in which case the urea N constitutes a valuable guide to surgical risk), lead poisoning, certain infections, cardiac failure, and so on. Relatively low figures for urea nitrogen are found in nephrosis (nonhemorrhagic nephritis with edema), which is probably of metabolic rather than renal origin.

The blood urea concentration has greater significance when interpreted with relation to urea excretion, as in the urea clearance test (Chapter 31).

**2. Method of Van Slyke and Cullen:<sup>36</sup> Principle.** Whole blood is treated with urease under optimal conditions for conversion of the urea to ammonium carbonate. The mixture is then made alkaline with potassium carbonate and aerated. In the

<sup>35</sup> In the original procedure of Folin and Svedberg, 1 ml. of gum ghatti solution (see Appendix) is added at this point. This is ordinarily not necessary and its use should be avoided if possible, since it decreases color intensity and alters the relationship between color intensity and concentration. If used, it must be added to both standard and unknown.

<sup>36</sup> Van Slyke and Cullen: *J. Biol. Chem.*, **11**, 211 (1914); **24**, 117 (1916).

original procedure, the aerated ammonia is absorbed in standard acid and the acid back-titrated with standard alkali. In the modification described here, the ammonia is absorbed in boric acid solution and titrated directly with standard acid.

**Procedure.**<sup>37</sup> Into a large test tube (200 × 28 mm., preferably thick-walled and lipless)<sup>38</sup> place 2 ml. of phosphate buffer, 5 drops of caprylic alcohol, and

FIG. 147. VAN SLYKE AND CULLEN AERATION APPARATUS.

0.5 ml. of 10 per cent urease solution. Add exactly 2 ml. of blood, mix gently, stopper loosely with a rubber stopper carrying the long inlet tube and the short outlet tube shown in Fig. 147, and allow to stand at room temperature for 10 minutes. This is Tube A. During the time of standing, prepare Tube B by placing 25 ml. of boric acid solution containing indicator in a second large test tube similar to the first, add a drop of caprylic alcohol, and stopper tightly with a rubber stopper likewise carrying inlet and outlet tubes.<sup>39</sup> Place in a test-tube rack or wooden block alongside Tube A, and connect the long inlet tube of B with the short outlet tube of A by means of a short length of rubber tubing,<sup>40</sup> as shown. When the 10-minute period is up, raise the stopper of A and add 5 ml. of a saturated solution of potassium carbonate down the side of the tube. Immediately replace the stopper and tighten it firmly in

place. Attach the long inlet tube of A by rubber tubing to a large test tube or wash bottle half-full of N sulfuric acid, plus a few drops of caprylic alcohol,

<sup>37</sup> Reagents Required: *Phosphate Buffer*. Dissolve 6 g. of monopotassium phosphate ( $\text{KH}_2\text{PO}_4$ ) and 2 g. of anhydrous disodium phosphate ( $\text{Na}_2\text{HPO}_4$ ) in water, dilute to 1 liter, and mix. Add a few drops of chloroform as preservative.

*Caprylic Alcohol*. Dispense from a dropping bottle.

*10 Per Cent Urease Solution*. Stir up 1 g. of urease powder in a little water, sufficient to make a paste, and then add water, a little at a time, with stirring, to make the final volume 10 ml. Keep in the refrigerator when not in use, and make up only enough for each day's use, discarding the remainder, if any. "Arlco" urease (Arlington Chemical Co., Yonkers, N.Y.) may also be used. The activity of each bottle of urease should be tested by running through the standardization procedure on a urea solution as described below.

*Boric Acid Solution, 2 Per Cent, with Indicator*. Dissolve 20 g. of reagent-grade boric acid in about 500 ml. of hot water, cool, add 2 ml. of 0.1 per cent bromocresol green in alcohol (the aqueous solution of the sodium salt may also be used), dilute to 1 liter, and mix. This solution need not be prepared accurately, and may be prepared in large volume sufficient for several weeks' use. If the color fades on standing, more indicator may be added to the remaining portion. Only bromocresol green indicator may be used, since in the presence of caprylic alcohol other indicators (e.g., methyl red) are sufficiently altered in tint so that comparison of the end point with a control, as described in the text, becomes impossible. The 2 per cent strength of boric acid is recommended rather than 4 per cent because of the better end point and because it has been found capable of absorbing all the ammonia likely to be present, even in an analysis of urine (see Chapter 31).

*Saturated Potassium Carbonate Solution*. To 900 g. of pure dry potassium carbonate add 1 liter of water. Stir to dissolve as completely as possible.

*Standard Sulfuric Acid Solution*. This is to be of such strength that 1 ml. represents 0.2 mg. of nitrogen. Theoretically, a 0.0143 N solution is required. Practically, it is better to standardize the acid against pure urea as described here and adjust to the required strength. Measure exactly 15.0 ml. of N sulfuric acid from a buret into a 1-liter volumetric flask, dilute to the mark with water, and mix. Prepare a standard urea solution containing 1.07 g. of pure dry urea in 1 liter. Analyze a 2-ml. portion of the urea solution by the procedure described in the text, replacing the blood by the urea solution, and titrating with the acid. Multiply

and so arranged that when air is drawn through *A* it must first bubble through the wash bottle, thus freeing it of any ammonia. Attach the short outlet tube of *B* by rubber tubing to a suitable source of suction (water pump or vacuum line). When everything is ready, turn on the suction carefully and draw air slowly through *A* and *B* for about one minute, then increase the rate of air passage until the air is passing through as rapidly as possible. Continue the aeration for one hour. At the end of this time, slow down the rate of air passage (but do not stop it entirely) and disconnect the tubes, starting at the point farthest removed from the source of suction, to prevent any effects of back pressure. Remove the stopper and tubes from *B*, rinse down the long tube with a little water, and place the stopper aside. Titrate the contents of *B* with the standard sulfuric acid, preferably using a buret of 10 ml. capacity. The end point is when the more or less blue solution is exactly restored to its original yellow-green shade. This is best seen by having a control tube similar to *B* and containing 25 ml. of the boric acid-indicator solution. The contents of *B* are titrated until they exactly match the color of the control solution. The end point is usually sensitive to about 0.02 ml. of the standard acid.

CALCULATION. The strength of the acid is such that 1 ml. represents 0.2 mg. of nitrogen. Since 2 ml. of blood are used for analysis, the calculation is as follows:

$$\text{ml. standard acid required} \times 10 = \text{mg. urea N per 100 ml. blood}$$

As many pairs of tubes as desired may be connected in series as described, thus permitting the carrying out of a number of determinations at the same time. According to Van Slyke and Cullen, 75 liters of air will remove the ammonia satisfactorily from a solution half-saturated with potassium carbonate. The time required for complete aeration thus depends upon the rate of air passage, and may be shorter than that specified. It may be established by treating portions of standard ammonium sulfate solution with an equal volume of saturated potassium carbonate solution and aerating into boric acid for varying periods of time, testing for completeness of recovery of the ammonia by titration as described.

The aeration inlet tubes should have a perforated bulb at the tip, as shown, to break up the air, but this is not absolutely necessary. If the blood foams excessively and more caprylic alcohol is of no value, a few ml. of ethyl alcohol may be added to the mixture.

**Interpretation.** See previous method.

**Variations of the Aeration Method.** The aerated ammonia may be absorbed in 25 ml. of 0.01 N sulfuric acid containing alizarin or methyl red indicator, and the excess acid titrated with 0.01 N sodium hydroxide,

15.0 by the number of ml. of acid used in the titration and divide the result by 5.00 to find the exact volume of N acid which must be diluted to 1 liter for the correct strength.

Thus if 4.77 ml. of acid were used in the titration,  $\frac{15.0}{5.00} \times 4.77 = 14.3$  ml. Discard the first

lot of acid and prepare a second using the correct volume of N sulfuric acid. Check by repeating the standardization; exactly 5.00 ml. of acid should be required in the titration. The acid solution is stable indefinitely and may be made up in large volume at one time.

<sup>38</sup> Both Kimble No. 49050 and Corning No. 7980 are satisfactory.

<sup>39</sup> It is good practice to have marked fitted stoppers for the *A* and *B* tubes separately and not to interchange them, thus avoiding the possibility of error due to traces of carbonate on an *A* inlet tube entering the boric acid of a *B* tube.

<sup>40</sup> Thick-walled stethoscope tubing is satisfactory. Cut in 6-inch lengths, scrub with a buret brush, then boil for 30 minutes in 10 per cent sodium hydroxide solution, making sure that the tubes are filled with the solution. Rinse thoroughly in tap water and distilled water. Do not use acid for washing the tubes.

as described in the original procedure of Van Slyke and Cullen. The aeration procedure may also be applied to the Folin-Wu filtrate after urease treatment, the liberated ammonia being absorbed in dilute acid and determined colorimetrically. The ammonia aerated from urease-treated whole blood may also be determined colorimetrically instead of by titration.

**3. Method of Karr:**<sup>41</sup> **Principle.** By the action of urease, the urea in a protein-free filtrate is converted to ammonium carbonate which is nesslerized in the presence of a protective colloid. The interference of peptones and amino acids (Folin and Wu) is regarded as so slight and uniform as not to influence the clinical value of the results.

**Procedure.**<sup>42</sup> Transfer 5 ml. of Folin-Wu blood filtrate to a test tube, and in a similar tube place 5 ml. of standard urea solution, containing 0.075 mg. of nitrogen. To each tube add 0.5 ml. of buffer solution and 5 drops of urease solution. Place in a bath at 50° C. for 15 minutes. Transfer the contents of each tube, with rinsings, to separate test tubes<sup>43</sup> graduated at 22.5 and 25 ml., and dilute with water to the 22.5-ml. mark. Add 3 drops of gum ghatti solution, followed by Nessler solution to the 25-ml. mark. Mix, allow to stand for 10 minutes, and read within the next 20 minutes, using either a colorimeter or photometer. For photometric measurement, follow the conditions specified on p. 547 for the determination of nonprotein nitrogen, setting the photometer to zero density with a blank prepared by treating 5 ml. of water with buffer, urease, etc., exactly as described above for a blood filtrate.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.075 \times \frac{100}{0.5} = \text{mg. urea N per 100 ml. blood}$$

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.075 \times \frac{100}{0.5} = \text{mg. urea N per 100 ml. blood}$$

**Interpretation.** See under method of Folin and Svedberg above.

<sup>41</sup> Karr: *J. Lab. Clin. Med.*, **9**, 3 (1924). The use of gum ghatti as a stabilizing colloid by Folin (*J. Biol. Chem.*, **81**, 231 (1929) in his sugar method (p. 575) suggested its application in the urea method to Looney (*J. Biol. Chem.*, **88**, 189 (1930).

<sup>42</sup> Reagents Required: *Standard Urea Solution.* Dissolve 0.3215 g. of pure dry urea in water and dilute to 500 ml. in a volumetric flask. Add a little chloroform or toluene as a preservative. This solution contains 0.3 mg. of urea nitrogen per ml. To prepare the working standard, dilute 5 ml. of stock standard to 100 ml. with water in a volumetric flask, and mix. Prepare fresh daily. This solution contains 0.075 mg. of urea nitrogen in 5 ml.

*Buffer Solution.* Dissolve 20 g. of crystalline sodium acetate in water, add 2.2 ml. of 10 per cent acetic acid, dilute to 100 ml. with water, and mix. Add a little toluene or chloroform as preservative.

*Urease Solution.* Place 15 g. of jack bean meal (obtainable from the Arlington Chemical Co., Yonkers, N.Y.), about 2 g. of "Permutit" (see Appendix), 16 ml. of 95 per cent alcohol, and 84 ml. of water in a 200-ml. flask. Shake more or less continuously for about 15 minutes. Pour onto a filter and allow to filter overnight in the refrigerator. Keep the filtrate in the cold, transferring a portion to a dropping bottle for daily use. Prepare fresh every three to four weeks, or when a blank analysis shows the presence of significant amounts of ammonia.

*Gum Ghatti Solution.* See Appendix.

*Nessler Solution.* The Koch-McMeekin preparation is recommended (see Appendix).

<sup>43</sup> Separate tubes for nesslerization are necessary because of the "poisoning" action of mercury on urease. When this is suspected in the conversion tubes they should be cleaned with strong nitric acid.

**4. Method of Leiboff and Kahn:**<sup>44</sup> **Principle.** The urea in the Folin-Wu blood filtrate is converted to ammonia by acid hydrolysis under pressure and directly nesslerized. The slight conversion of nonurea substances to ammonia is unimportant clinically. By the elimination of urease, turbidity after nesslerization is claimed to be avoided even with filtrates high in urea.

## DETERMINATION OF CREATININE

**Introduction.** Blood creatinine is ordinarily determined by reaction in a protein-free filtrate with alkaline picrate to form a red color (the Jaffé reaction), which is then compared with a standard. A color reaction of creatinine with dinitrobenzoate has also been described.<sup>45</sup> It is well recognized that the Jaffé reaction is by no means specific for creatinine, and that other substances are present in blood (chiefly in the red cells) which contribute to the color, so that results on whole blood filtrates are undoubtedly too high.<sup>46</sup> Practically all of the chromogenic material in plasma, however, appears to be creatinine, and therefore plasma is preferred to whole blood for analysis. Most of the results in the literature have been obtained on whole blood. A specific method for creatinine determination appears to be the measurement by the Jaffé reaction before and after treatment with a bacterial preparation which destroys creatinine.<sup>47</sup>

**Method of Folin and Wu:**<sup>48</sup> **Principle.** A portion of the blood filtrate is treated with alkaline picrate solution and the color developed is compared in a colorimeter or photometer with that produced by a known amount of creatinine under the same conditions.

**Procedure.**<sup>49</sup> Transfer 10 ml. of 1:10 tungstic acid filtrate of whole blood or plasma (preferably the latter) to a small flask or test tube. In a second container, place 5 ml. of standard creatinine solution, containing 0.03 mg. of creatinine, and add 15 ml. of water. Add 5 ml. of freshly prepared alkaline picrate reagent to the blood filtrate, and 10 ml. to the diluted creatinine

<sup>45</sup> Benedict and Behre: *J. Biol. Chem.*, **114**, 515 (1936); Langley and Evans: *ibid.*, **115**, 333 (1936).

<sup>46</sup> Hunter and Campbell: *J. Biol. Chem.*, **32**, 195 (1917); Behre and Benedict: *ibid.*, **52**, 11 (1922); **117**, 415 (1937); Miller and Dubos: *ibid.*, **121**, 447, 457 (1937); Gaebler and Abbott: *ibid.*, **123**, 119 (1938).

<sup>47</sup> Miller and Dubos: *loc. cit.*; Allinson: *J. Biol. Chem.*, **157**, 169 (1945).

<sup>48</sup> Folin and Wu: *J. Biol. Chem.*, **38**, 81 (1919). See also Peters: *J. Biol. Chem.*, **146**, 179 (1942); Bonsnes and Taussky: *ibid.*, **158**, 581 (1945).

<sup>49</sup> Reagents Required: *Standard Creatinine Solution.* Prepare a *stock standard* by dissolving 1 g. of pure dry creatinine in 0.1 N hydrochloric acid and diluting to 1 liter with the acid. This solution is stable indefinitely, and contains 1 mg. of creatinine per ml. To prepare the *working standard*, transfer 3 ml. of stock standard, containing 3 mg. of creatinine, to a 500-ml. volumetric flask, add 50 ml. of 0.1 N hydrochloric acid, dilute with water to 500 ml., and mix. This standard contains 0.03 mg. of creatinine in 5 ml., and is stable for a week or more if preserved by the addition of a few drops of toluene.

*Alkaline Picrate Reagent.* (a) Prepare a saturated solution of purified picric acid (see Appendix). It is essential that this solution be *saturated*, otherwise serious error may result. A 10-ml. portion, titrated with 0.1 N alkali in the presence of phenolphthalein as indicator, should require 5.2 to 5.4 ml. of alkali for neutralization. (b) To prepare the fresh alkaline picrate reagent, transfer 25 (or 50) ml. of the saturated picric acid solution to a flask, add 5 (or 10) ml. of 10 per cent sodium hydroxide solution, and mix. Use within a short time after preparing. On standing, crystals may form in the solution which do not impair its effectiveness but render measurement difficult.

standard. Mix, and allow to stand for 15 minutes for complete color development. Read in the colorimeter or photometer within the next 15 minutes.

For colorimetric measurement, first match the standard against itself carefully, and then compare with the unknowns in the usual way. For photometric measurement, transfer the solutions to suitable containers and determine the densities in the photometer at 520  $m\mu$  (see Fig. 148). Set the photometer to zero density with water alone. Determine the density of a blank prepared by treating 10 ml. of water with 5 ml. of the alkaline picrate reagent, and subtract this value from the observed densities of standard and unknown to obtain their true values.

FIG. 148. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED IN FOLIN-WU BLOOD CREATININE METHOD.

Alkaline picrate alone (*bl*); alkaline picrate plus 0.03 mg. creatinine (*a*); plus 0.06 mg. creatinine (*b*). Solution depth, 1 cm.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{mg. creatinine in standard} \times \frac{100}{1} \times \frac{15}{30} \\ = \text{mg. creatinine per 100 ml. blood or plasma}$$

In connection with this calculation, it is to be noted that the standard is made up to twice the volume of the unknown, so that a volume correction factor ( $1\frac{5}{30}$ ) is introduced. The standard specified corresponds to a blood creatinine of 1.5 mg. per cent, and is satisfactory for the range of 1 to 2 mg. per cent *only*, because of the presence of the high blank color of the alkaline picrate and the significant deviation from Beer's law (see p. 557) shown by this color reaction. It is good practice, therefore, to prepare several standards at different concentration levels, to provide for values outside the indicated range. If a high creatinine should be encountered without several standards ready, the determination may be saved by diluting the unknown with an appropriate amount of the alkaline picrate solution which has first been diluted with two volumes of water, to preserve equality of picric acid and alkali concentration. It is better, however, to repeat the analysis if possible, using less filtrate plus water to 10 ml., correcting the calculations accordingly.

*For photometric measurement*, values up to about 5 mg. per cent blood creatinine may be calculated as follows:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{mg. creatinine in standard} \times \frac{100}{1} \times \frac{15}{30} \\ = \text{mg. creatinine per 100 ml. blood or plasma}$$

For higher values, repeat the analysis with 5 ml. of filtrate plus 5 ml. of water, and multiply the results by 2. At 520  $m\mu$  and in a 1-cm. cuvette, the density of the standard described, corrected for the blank, is approximately 0.050.

This calculation is an *approximation* only, suitable for routine clinical purposes but not for precise work, since it is based on Beer's law, and the creatinine color does not follow Beer's law exactly at any concentration ordinarily encountered. For more exact work, a calibration curve relating observed densities to concentration must be prepared and results read from this curve. To obtain such a curve, prepare a standard creatinine solution which is twice as strong as that used in the procedure, by transferring 6 ml. of the stock 0.1 per cent creatinine solution to a 500-ml. volumetric flask, adding 50 ml. of 0.1 N acid, and diluting to the mark with water. This solution contains 0.06 mg. of creatinine in 5 ml. Transfer the following amounts of this solution (preferably in duplicate) to small flasks: 0.0, 5.0, 10.0, 15.0, and 20.0 ml. Add sufficient water to each flask to make the final volume 20 ml., and then add 10 ml. of alkaline picrate reagent to each. Mix, allow to stand 15 minutes, and determine the densities in the photometer under the conditions described in the text. The first flask is a blank; subtract its average value from the other average values to obtain their true densities. The amounts of creatinine in the various flasks are 0.06, 0.12, 0.18, and 0.24 mg., respectively, corresponding under the conditions of analysis to blood creatinine contents of 3, 6, 9, and 12 mg. per cent. Plot the true densities against the equivalent mg. per cent concentrations on cross-section paper and draw a smooth curve to include all the points. A curve similar to that shown in Fig. 149 should be obtained. From such a curve, the concentration of an unknown may be read off if its density has been established.

In using such a curve, it is important to remember that it is valid only if the analysis of an unknown is carried out under conditions similar to those prevailing at the time the curve was established. In general, the calibration for one photometer is not applicable to another instrument, even of the same make, and changing the wavelength setting or filter will influence the curve. The curve should be checked when a new lot of saturated picric acid<sup>50</sup> is prepared, although correcting for the blank as indicated will ordinarily take care of slight variations in the color of the alkaline picrate reagent. Time control and temperature control are important; the curve at 30° C. is not the same as at 20°. All of these precautions are necessary for obtaining accurate results.

**Interpretation.** Creatinine is the least variable nitrogenous constituent of the blood, in which it exists to the extent of 1 to 2 mg. per 100 ml. of whole blood; the average value for plasma is nearer 1 mg. per cent. In early nephritis, values of from 2 to 4 mg. are noted, and in chronic hemorrhagic nephritis with uremia, 4 to 35 mg. Creatinine is more readily excreted by the kidneys than urea or uric acid, and an increase of creatinine to 4 or 5 mg. or over per 100 ml. is evidence of marked impairment of kidney function. Such high creatinine values in chronic hemor-

FIG. 149. TYPICAL CALIBRATION CURVE FOR BLOOD CREATININE DETERMINATION, AT 520  $m\mu$ , 1 CM. SOLUTION DEPTH.

<sup>50</sup> Peters (*loc. cit.*) recommends a picric acid solution containing 11.75 g. per liter, rather than a saturated solution, to minimize differences in solubility of picric acid at summer and winter temperatures.

rhagic nephritis indicate an unfavorable prognosis, although high values may obtain in acute cases over long periods.

## DETERMINATION OF CREATINE

**Introduction.** The creatine of blood is ordinarily determined by the Folin-Wu procedure of heating the protein-free filtrate with acid, which converts creatine to creatinine. The total creatinine present is then determined by the procedure used for blood creatinine. The value for preformed creatinine, as established by separate analysis, is subtracted from the total creatinine value, to give the amount of creatine, expressed as creatinine. There is no satisfactory method for the direct determination of blood creatine. The specificity of the method based on acid treatment and the Jaffé reaction for creatinine is open to question. Increased specificity is undoubtedly obtained by the use of the creatinine-destroying bacteria of Miller and Dubos;<sup>51</sup> few applications of this principle to knowledge of blood creatine have as yet been made.

**Procedure.** Transfer 5 ml. of a 1:10 tungstic acid filtrate of whole blood to a test tube graduated at 25 ml. Add 1 ml. of normal hydrochloric acid. Cover the mouth of the test tube with tin foil and heat in the autoclave to 130° C. for 20 minutes or to 155° C. for 10 minutes. Cool. Add 5 ml. of freshly prepared alkaline picrate solution (as used for blood creatinine determination) and let stand for 8 to 10 minutes, then dilute to 25 ml. At the same time, prepare a standard creatinine solution by adding to 10 ml. of creatinine solution, containing 0.06 mg. of creatinine, in a 50-ml. volumetric flask, 2 ml. of normal acid, and 10 ml. of the alkaline picrate reagent, and after 10 minutes, diluting to 50 ml. Read in the colorimeter or photometer as described for the determination of blood creatinine (p. 556). The blank for photometric measurement is prepared by treating 10 ml. of water in a 50-ml. volumetric flask with 2 ml. of acid and 10 ml. of alkaline picrate reagent and diluting to 50 ml. with water.

In the case of uremic bloods containing large amounts of creatinine, 1, 2, or 3 ml. of blood filtrate, plus water enough to make approximately 5 ml., are substituted for the 5 ml. of filtrate, and calculations corrected accordingly.

**CALCULATION.** *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.06 \times \frac{100}{0.5} \times \frac{25}{50} = \text{mg. "total creatinine" per 100 ml. blood}$$

Subtract the preformed creatinine content, as determined by separate analysis (p. 555), from the "total creatinine," to obtain the creatine content, expressed as creatinine. The same precautions as were described for the determination of blood creatinine, concerning deviation from Beer's law and the use of several standards if necessary, must be observed.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.06 \times \frac{100}{0.5} \times \frac{25}{50} = \text{mg. "total creatinine" per 100 ml. blood}$$

Determine creatine by subtracting preformed creatinine value as described above.

<sup>51</sup> Allinson: *J. Biol. Chem.*, **157**, 169 (1945). For application of the bacterial method to the determination of creatine in tissues, see Miller, Allinson, and Baker: *J. Biol. Chem.*, **130**, 383 (1939); Borsook and Dubnoff: *ibid.*, **132**, 559 (1940).

As with the determination of creatinine, the calculation given is only an approximation because of deviation from Beer's law, and for precise results a calibration curve similar to that described on p. 557 should be constructed and used. The calibration curve prepared for the preformed blood creatinine determination cannot be used here because of the presence of acid and the different proportion of alkaline picrate used. In preparing this curve, remember that only 5 ml. of filtrate are used for analysis instead of 10 ml. as in the creatinine determination, so that a given amount of creatinine in the standard corresponds to twice as high a total creatinine content per 100 ml. of blood as in the calibration for preformed creatinine. Thus the standard described, containing 0.06 mg. of creatinine in a final volume of 50 ml., is equivalent in an analysis to a total blood creatinine of 6 mg. per cent, with other amounts in proportion.

**Interpretation.** Blood creatine content as determined by this and other methods ranges between 3 to 7 mg. per 100 ml. of whole blood. The creatine of blood is found almost entirely in the red cells, variations in cell count therefore presumably influencing results. Except in the case of infants and pregnant women, the amount of creatine in plasma is quite small; Allinson (*loc. cit.*) reports values ranging from 0.4 to 0.8 mg. per cent.<sup>52</sup> No significant variations have as yet been associated with pathological conditions, so the determination has little clinical value at the present time. Increases have been noted after severe muscular injury and following experimental removal of the kidneys.

## DETERMINATION OF URIC ACID

**Introduction.** Blood uric acid is ordinarily determined by colorimetric procedures based upon the reaction between uric acid and certain complex phosphotungstic acid reagents (or their equivalent), usually in the presence of cyanide,<sup>53</sup> to form a blue color. Procedures utilizing the reducing action of uric acid on ferricyanide have also been described.<sup>54</sup> The determination of blood uric acid has been the subject of much criticism and study. It appears probable that a portion of the blood uric acid is lost during precipitation of the proteins; up to now, there appears to be no simple way to avoid this.<sup>55</sup> The use of the various color reagents on a blood filtrate directly, without preliminary separation of interfering material, is felt by many investigators to be unsound, because of both the nonspecificity of the color reaction and the possible presence of substances which inhibit color development with uric acid itself. A combination of these effects (one tending to increase color, the other decreasing it) is felt by some to be responsible for the apparently satisfactory results obtained in some procedures. Interfering material appears to be present largely in the red cells of blood; the use of plasma or serum for analysis is therefore gaining ground and is to be preferred. Increased specificity is also obtained by separating the uric acid from interfering material prior to analysis. Color development before and after treatment with preparations of the enzyme *uricase*, which oxidizes uric acid, has also been proposed

---

<sup>52</sup> See also Tierney and Peters: *J. Clin. Invest.*, **22**, 595 (1943).

<sup>53</sup> For a procedure not involving the use of cyanide, see Kern and Stransky: *Biochem. Z.*, **290**, 419 (1937).

<sup>54</sup> See Bulger and Johns: *J. Biol. Chem.*, **140**, 427 (1941).

<sup>55</sup> See, however, Kern and Stransky (*loc. cit.*).

as a basis of specificity.<sup>56</sup> Of the three procedures described below, two are based on separation of interfering material before color development. The third, the method of Brown, is a direct method which appears to be as satisfactory as any that have been described, and simpler than most.

**Method of Folin (Isolation Procedure):<sup>57</sup> Principle.** Uric acid is precipitated as silver urate, directly from the blood filtrate. The uric acid is set free by means of acid chloride solution and determined colorimetrically or photometrically after the addition of phosphotungstic acid, which gives a blue solution.

**Procedure.<sup>58</sup> Transfer 5 ml. of the blood filtrate<sup>59</sup> to a centrifuge tube. Add 2 ml. of the acid silver solution. Centrifuge at once. All the uric acid, down**

---

<sup>56</sup> Blauch and Koch: *J. Biol. Chem.*, **130**, 443 (1939). For a description of a uricase procedure applied to the determination of uric acid in urine, see Chapter 31, "Urine: Quantitative Analysis."

<sup>57</sup> Folin: *J. Biol. Chem.*, **101**, 111 (1933); **106**, 311 (1934). The Folin "direct method" is similar to the procedure described here and requires the same reagents, except that the precipitation with acid silver solution is omitted. A 5-ml. portion of the blood filtrate is treated directly with the cyanide-urea solution, uric acid reagent, etc., exactly as described in the text. Calculations and directions for photometric and colorimetric measurement are the same.

<sup>58</sup> Reagents Required: *Acid Silver Solution*. To 5 ml. of 85 per cent lactic acid add 100 ml. of water and 5 g. of  $\text{Na}_2\text{CO}_3$  and boil. Dissolve 25 g. of silver nitrate in about 700 ml. of water, add the partly neutralized lactic acid solution, and dilute to 1 liter. After a few days' exposure to sunlight and filtering, this reagent keeps fairly well. When used only occasionally, however, it should be filtered before using.

*Standard Uric Acid Solution*. The solution made as follows will keep for at least five years. Weigh out on a watch glass exactly 1 g. of uric acid and transfer it to a liter volumetric flask by means of a not too small, dry funnel. Tap the funnel, so as to transfer nearly the whole of the uric acid to the flask. Transfer 0.6 g. of lithium carbonate to a 250-ml. Florence flask, add 150 ml. of water; shake about five minutes until dissolved. Some insoluble material remains, and it is usually best to filter. Heat the solution or filtrate to 60° C. Also, warm the liter flask under running warm water. Pour the warm lithium carbonate solution into the liter flask, incidentally washing into it the traces of uric acid which adhered to the watch glass and funnel. Shake so as to dissolve the uric acid promptly. A little additional warming under hot tap water is permissible. The lithium carbonate solution is not always perfectly clear even when filtered, and one should not mistake this little turbidity for undissolved uric acid and keep warming and shaking too long. In five minutes all of the uric acid should be dissolved. Shake the flask under cold running water without undue delay. Add 20 ml. of 40 per cent formalin, and half fill the flask with distilled water. Finally add, from a pipet, rather slowly and with shaking, 25 ml. of normal sulfuric acid. Dilute to volume, mix thoroughly, and transfer to a clean, tightly stoppered bottle. This stock solution, containing 1 mg. of uric acid per ml., should be kept away from light.

To prepare the working standard, dilute 1 ml. of the stock solution, with water only, to 250 ml. It behaves exactly like a lithium carbonate solution of uric acid and keeps perfectly for many days. (5 ml. = 0.02 mg. uric acid.)

*Urea-Cyanide Solution (Poisonous!)*. Transfer 75 g. of Merck's Blue Label sodium cyanide to a 2-liter beaker, add 700 ml. of water, and stir until the cyanide is completely dissolved. Add 300 g. of urea and stir. Then add 4 to 5 g. of calcium oxide and stir for about 10 minutes. Filter, at once if necessary for immediate use, but preferably not until the next day. To the filtrate add about 2 g. of powdered lithium oxalate, shake occasionally for 10 to 15 minutes, and filter.

*Uric Acid Reagent*. Transfer 100 g. of sodium tungstate (free from molybdate, cf. footnote 59 below) to a 500 ml. Florence flask. Mix 32 to 33 ml. of 85 per cent phosphoric acid with 150 ml. of water. Pour the resulting solution on to the tungstate and mix. Add a few pebbles and boil very gently over a microburner for 1 hour. Loss of liquid during the boiling is prevented by using, as a condenser, a funnel holding a 200-ml. flask filled with cold water. At the end of the boiling period decolorize with a little bromine water, boil off the excess bromine, cool, and dilute to 500 ml.

If the reagent so obtained is not perfect (in other words, if it gives a blank with Merck's urea-cyanide or with urea-cyanide plus tyrosine), add 3 to 5 g. of sodium tungstate (but

to the last trace, will now be in the precipitate. Decant the supernatant solution as completely as possible, and add 1 ml. of a 10 per cent solution of sodium chloride in 0.1 N hydrochloric acid. Stir *thoroughly* with a fine glass rod; add 4 ml. of water, and stir again. Centrifuge. Pour the supernatant solution as completely as possible into a test tube graduated at the 25-ml. mark. Remove the last drop by touching the lip of the centrifuge tube to the side of the graduated test tube. Prepare two standards by placing 3 ml. (plus 2 ml. of water) and 5 ml. respectively of standard uric acid solution, containing 0.02 mg. of uric acid in 5 ml., in separate test tubes, and for photometric measurement prepare a blank tube containing 5 ml. of water only. To each tube add 10 ml. of urea-cyanide solution (*Poisonous! from a buret*) and mix well by lateral shaking. Add 4 ml. of the uric acid reagent to each tube, mix well by lateral shaking, and note the time. Let stand for 20 minutes, dilute to the 25-ml. mark with water, stopper, and mix by inversion. Read in the usual way within the next half-hour in the colorimeter or photometer. For photometric measurement, determine the densities at 420  $m\mu$ , setting the photometer to zero density with the blank.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{mg. uric acid in standard} \times \frac{100}{0.5} \\ = \text{mg. uric acid per 100 ml. blood or plasma}$$

Read the unknown against the standard which most closely matches it on inspection, and substitute the proper value for the uric acid content of the standard (0.012 or 0.020, as the case may be) in the calculation formula above. The stronger standard corresponds to a blood with 4 mg. per cent uric acid; up to 8 mg. per cent may be read satisfactorily. For higher values, instead of using the entire supernatant from the acid extraction of the precipitated silver urate as described, pipet out 2.5 ml. at this point, add 2.5 ml. of water, and continue with the addition of urea-cyanide, color development, etc., as described, multiplying the final results by 2.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{mg. uric acid in standard} \times \frac{100}{0.5} \\ = \text{mg. uric acid per 100 ml. blood or plasma}$$

Either standard may be used, therefore only one is necessary. At 420  $m\mu$ , and in a 1-cm. cuvette, the density of the stronger standard, corresponding to 4 mg. per cent blood uric acid, is approximately 0.500. Up to 8 mg. per cent may be accurately read under these conditions. For higher values, or with deeper cuvettes, use half of the supernatant fluid from the acid extraction as described above under colorimetric measurement, and multiply the results by 2.

---

no more) and boil for another 10 to 15 minutes, then cool, and decolorize as before. The addition of a little extra tungstate and the short second boiling can also be made without first testing the reagent for a blank.

<sup>59</sup> The tungstic acid deproteinization preceding estimation of uric acid by this method must be made with sodium tungstate entirely free from molybdate. A product meeting this specification is made by the Mallinckrodt Chemical Co. The absence of molybdate should be confirmed on each new batch of sodium tungstate by applying the following xanthate test (Folin and Trimble: *J. Biol. Chem.*, **60**, 473 (1924)): Dissolve 1 g. of sodium tungstate in 5 to 10 ml. of water. The solution should be alkaline. Add about 0.2 g. of solid potassium ethyl xanthate (Eastman, or prepare as directed in original paper). Shake until dissolved. Add dropwise with shaking, 20 per cent  $H_2SO_4$ , until the curdy tungstic acid precipitate dissolves. In the presence of molybdenum, as the solution becomes definitely acid, a pink to deep plum color forms. The colored compound, molybdenum xanthate, is soluble in chloroform.

**Interpretation.**<sup>60</sup> Normal human whole blood usually contains from 2 to 3.5 mg. of uric acid per 100 ml. by this method. The normal range for plasma is 3 to 5 mg. per cent. In early nephritis values of from 3 to 10 mg. may be noted, and in advanced cases values as high as 25 mg. are observed. The determination of blood uric acid is generally regarded as an unsatisfactory index of renal impairment since its level may be affected by a chemical destructive process as well as by excretion, which might account for the observed inconsistencies between hyperuricemia and other nonprotein nitrogen retention.

In gout, high uric acid values (4 to 10 mg.) are usually found. Determination of uric acid is of *diagnostic value* in gout prior to the stage of tophi formation, particularly since normal values, in the absence of salicylate or dietary therapy, would ordinarily exclude a positive diagnosis. However, uric acid is similarly increased in early nephritis and many cases of gout with high uric acid values also show defective kidney function by other tests. The same difficulty is met with in considering the high values (2 to 8 mg.) obtained in other arthritic conditions, usually associated with increases in urea also. The existence of nephritis in such cases has not been entirely excluded and many typical cases of arthritis show values below 3 mg. Salicylates and atophan (cincophen) tend to reduce the uric acid content of the blood.

The excessive breakdown of nuclear material in leukemia is accompanied by elevated uric acid values. In addition to the numerous conditions resulting in renal damage, such as mercury or lead poisoning, eclampsia, acute infections, malignancy, etc., the blood uric acid is also increased in certain cardiac conditions which ultimately involve the kidneys.

**2. Method of Newton:**<sup>61</sup> **Principle.** Interfering material in the blood filtrate is removed by the acid silver chloride precipitation method of Benedict and Behre.<sup>62</sup> The uric acid remaining is determined colorimetrically by reaction at room temperature in the presence of cyanide with a special arsenotungstate reagent.

**Procedure.**<sup>63</sup> The blood proteins are precipitated with the molybdotungstic acid reagent of Benedict and Newton rather than by the Folin-Wu tungstic acid method, although this latter filtrate may also be used. Transfer 1 volume of blood to a small flask and add 7 volumes of water to make. Add 1 vol-

<sup>60</sup> See reviews by Folin, Berglund, and Derick: *J. Biol. Chem.*, **60**, 361 (1924), and Rose: *Physiol. Revs.*, **3**, 544 (1923). See also Myers and Muntwyler: *Ann. Rev. Biochem.*, **9**, 303 (1940).

<sup>61</sup> Newton: *J. Biol. Chem.*, **120**, 315 (1937).

<sup>62</sup> Benedict and Behre: *J. Biol. Chem.*, **92**, 161 (1931). For the complete uric acid procedure of these authors, see the eleventh edition of this book.

<sup>63</sup> Reagents Required: *For Protein Precipitation: Tungstomolybdate Solution.* Boil 10 g. of reagent-grade ammonia-free molybdic acid with 50 ml. of normal sodium hydroxide for 4 to 5 minutes. Filter, and wash the residue on the filter with 150 ml. of hot water. Cool the filtrate and washings and add to a solution of 80 g. of sodium tungstate dissolved in 600 ml. of water. Dilute to 1 liter and mix. *0.62 N Sulfuric Acid.* Dilute 620 ml. of N sulfuric acid to 1 liter with water, and mix. Both these solutions are stable indefinitely.

*Acid Lithium Chloride.* Dissolve 7.5 g. of lithium chloride in water, add 35 ml. of concentrated hydrochloric acid, dilute to 1 liter with water, and mix. Stable indefinitely.

*Silver Nitrate Solution.* Dissolve 29 g. of reagent-grade silver nitrate in water, dilute to 1 liter, and mix. Keep in a brown bottle.

*"Acid Blank" Solution (for photometric measurement only).* Dilute 7 ml. of concen-

ume of tungstomolybdate solution followed by 1 volume of 0.62 N sulfuric acid, with shaking. Allow to stand for a few minutes, then pour onto a dry filter and collect the filtrate in a small dry flask. For plasma or serum, use 8 volumes of water and 0.5 volume of the tungstomolybdate and acid.

Transfer 5 ml. of the 1:10 filtrate prepared as described to a 15-ml. centrifuge tube, add 1 ml. of acid lithium chloride, and mix. Add 1 ml. of silver nitrate solution and shake well. Centrifuge at once and pour the supernatant fluid<sup>64</sup> into a test tube, allowing time for complete drainage. Touch the lip of the centrifuge tube to the test tube to obtain the last drop. In a second test tube place 5 ml. of the standard uric acid solution, containing 0.02 mg. of uric acid, and add 2 ml. of water. For photometric measurement prepare a third tube containing 5 ml. of "acid blank" solution plus 2 ml. of water. To each tube add *from a buret* 3 ml. of the cyanide-urea reagent (*poisonous*), mix by lateral shaking, and follow with 1 ml. of the diluted lithium arsenotungstate reagent *from a buret* (*poisonous*). Stopper and mix by inversion. Allow to stand 10 minutes, and then read in a colorimeter or photometer. For photometric measurement, determine the densities at 520 m $\mu$ , setting the photometer to zero density with the blank.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.02 \times \frac{100}{0.5} = \text{mg. uric acid per 100 ml. blood or plasma}$$

With the standard at 15 mm., readings of the unknown between 10 mm. and 30 mm. are reliable. For higher values, use less filtrate plus water to 5 ml. in the acid silver chloride precipitation, and correct the calculations accordingly.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.02 \times \frac{100}{0.5} = \text{mg. uric acid per 100 ml. blood or plasma}$$

---

trated hydrochloric acid to 1 liter with water and mix.

*Cyanide-Urea Reagent (Poisonous!).* Dissolve 100 g. of urea in 500 ml. of water. Add 25 g. of reagent-grade sodium cyanide and stir to dissolve. This solution is usable for 1 month or so. Fresh solution must be prepared if color develops in a blank test run as described for photometric measurement in the text.

*Lithium Arsenotungstate Reagent (Poisonous!).* Dissolve 100 g. of reagent-grade sodium tungstate in 500 ml. of water, and add 140 g. of reagent-grade arsenic pentoxide. Boil under a reflux condenser for 1 hour. Remove the condenser and continue boiling until the volume is reduced to about 200 ml. Pour this solution onto 100 g. of solid lithium chloride in a beaker. Stir until all of the lithium chloride has gone into solution. Chill the contents of the beaker to at least 10° C. for 2 hours but no longer. Filter off the precipitated lithium arsenotungstate by suction and suck as dry as possible. Excess water may also be removed by pressing the precipitate between filter papers. About 130 g. of material should be obtained. Dissolve in water and dilute to 500 ml. This stock solution keeps indefinitely. Before use, a portion is diluted with 4 volumes of water. This diluted reagent is used in the procedure. The salt may also be prepared in quantity, preserved in the dry state, and dissolved in water as needed.

*Standard Uric Acid Solution (Benedict).* A stock solution is prepared as follows: Dissolve 9 g. of disodium hydrogen phosphate and 1 g. of sodium dihydrogen phosphate (pure crystalline salts) in about 200 to 300 ml. of hot water. If not perfectly clear, filter. Dilute the clear solution to 500 ml. with hot water and pour upon exactly 200 mg. of pure uric acid suspended in a few ml. of water in a liter volumetric flask. Mix until solution is complete. Cool, add exactly 1.4 ml. of glacial acetic acid, dilute to mark, and mix. Add 5 ml. of chloroform to prevent bacterial or mold growth. (5 ml. = 1 mg. of uric acid.) The *working standard* is prepared fresh weekly as follows: Transfer 10 ml. of stock solution to a 500 ml. volumetric flask, dilute to 400 ml.; add 3.5 ml. of concentrated hydrochloric acid, dilute to mark, and mix. (5 ml. = 0.02 mg. of uric acid.)

<sup>64</sup> A slight opalescence may be noted, due to a trace of colloidal silver chloride, but this disappears after the addition of the cyanide solution, and does not affect the accuracy of the results.

At 520  $m\mu$ , and in a 1-cm. cuvette, the standard described has a density of 0.180 (Fig. 150). Under these conditions, measurements are reliable up to 10 mg. per cent uric acid. For higher values, or with a deeper cuvette, use less filtrate plus water to 5 ml. in the acid silver chloride precipitation, and correct the calculations accordingly. The color in this procedure does not reach a constant value, changing gradually in intensity with time. This change takes place at about the same rate in the standard and in the unknowns. In serial analyses it is necessary, therefore, to reread the standard at suitable intervals and to calculate results in terms of the density of the standard at approximately the time the density of an unknown is determined.

FIG. 150. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED IN NEWTON BLOOD URIC ACID METHOD.

For standards containing 0.01 mg. uric acid (a), and 0.02 mg. uric acid (b). Solution depth, 1 cm.

**Interpretation.** Results on human blood by this procedure are closely similar to those obtained by the previous method. Occurrence of turbidity is much less frequent than for other methods. For further interpretation see p. 562.

**3. Method of Brown:<sup>65</sup> Principle.** The tungstic acid filtrate is treated directly with a special uric acid reagent in the presence of optimal amounts of cyanide-urea solution. The color developed is compared with that of a uric acid standard treated similarly.

**Procedure.<sup>66</sup>** Transfer 2 ml. of 1:10 tungstic acid filtrate to a test tube or cylinder graduated at 10 ml. In a similar tube place 2 ml. of standard uric acid solution containing 0.005 mg. of uric acid, and for photometric measurement prepare a third or "blank" tube containing 2 ml. of water. To each

<sup>65</sup> Brown: *J. Biol. Chem.*, 158, 601 (1945).

<sup>66</sup> Reagents Required: *Sodium Cyanide Solution, 12 Per Cent.* Dissolve 12 g. of pure sodium cyanide in water in a beaker, transfer to a 100-ml. cylinder, add water to the mark, and mix with a stirring rod. *Handle this solution carefully, as it is extremely poisonous.* Keep in the refrigerator. It should be usable for about 2 weeks. Bring to room temperature before transferring a portion to a buret for daily use.

*Urea Solution.* Dissolve 50 g. of urea in sufficient water to make 100 ml. This solution keeps indefinitely at room temperature.

*Uric Acid Reagent.* Dissolve 100 g. of reagent-grade sodium tungstate and 20 g. of anhydrous disodium hydrogen phosphate in about 150 ml. of water in a flask with the aid of heat. Mix 25 ml. of concentrated sulfuric acid with about 75 ml. of water and pour the warm solution, slowly and with shaking, into the flask. Place a funnel in the mouth of the flask and in the funnel place a 200-ml. flask filled with ice water. Heat the mixture in the

tube add 2 ml. of cyanide solution *from a buret; this reagent is highly poisonous and must never be dispensed from a pipet*. Mix by lateral shaking, and add 2 ml. of urea solution to each tube. Again mix. Finally add 1 ml. of the uric acid reagent, mix by lateral shaking, and allow to stand at room temperature for 50 minutes. Dilute to the 10-ml. mark with water, stopper, and mix by inversion. Read in the colorimeter or photometer in the usual way. For photometric measurement, read at 520  $m\mu$ , setting the photometer to zero density with the blank.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.005 \times \frac{10}{2} \times 100 = \text{mg. uric acid per 100 ml. blood}$$

The standard described corresponds to a blood uric acid content of 2.5 mg. per cent. For values over 5 mg. per cent, repeat the analysis using 1 ml. of filtrate plus 1 ml. of water, and multiply the results by 2.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.005 \times \frac{10}{2} \times 100 = \text{mg. uric acid per 100 ml. blood}$$

At 520  $m\mu$  and in a 1-cm. cuvette, the density of the standard (corrected for the blank) is approximately 0.200. Satisfactory agreement with Beer's law is found up to blood concentrations of 6 mg. per cent. For higher values, or with deeper cuvettes, use 1 ml. of filtrate plus 1 ml. of water for the analysis, and multiply the results by 2.

**Interpretation.** By this method human whole blood shows a normal range of 2.2 to 3.5 mg. per cent for males and 1.9 to 2.9 mg. per cent for females. Results are lowered by only about 10 per cent or less when the uricase procedure (see p. 559) is applied to establish specificity. For further interpretation, see p. 562.

## DETERMINATION OF AMINO ACIDS

**Principle.** The color developed by the reaction between amino acids and  $\beta$ -naphthoquinone-4-sulfonic acid in alkaline solution is the basis of this method. Originally proposed by Folin, the method was considerably improved by Danielson,<sup>67</sup> and this procedure is essentially the one described here, with heating to develop the color as suggested by Sahyun,<sup>68</sup> and with photometric measurement according to Frame, Russell, and Wilhelmi.<sup>69</sup>

**Procedure.**<sup>70</sup> Prepare a tungstic acid filtrate of whole blood or plasma at a 1:10 dilution in the usual way (see p. 543). Transfer 5 ml. of protein-free

---

flask to boiling and boil gently for 1 hour, the funnel arrangement serving as a condenser. Cool and transfer to a 1-liter volumetric flask with rinsings, dilute to the mark with water, and mix.

*Uric Acid Standard.* Dilute 1 ml. of the Folin stock uric acid standard, containing 1 mg. of uric acid (see footnote 58) to 400 ml. with water and mix. This solution contains 0.005 mg. of uric acid in 2 ml., and keeps well for several days, particularly if kept cold.

<sup>67</sup> Danielson: *J. Biol. Chem.*, **101**, 505 (1933).

<sup>68</sup> Sahyun: *J. Lab. Clin. Med.*, **24**, 548 (1938-1939).

<sup>69</sup> Frame, Russell, and Wilhelmi: *J. Biol. Chem.*, **149**, 255 (1943). See also Russell: *J. Biol. Chem.*, **156**, 467 (1944), for a slightly modified procedure, claimed to give better results.

<sup>70</sup> Reagents Required: *Amino Acid Standard Solution.* A mixed standard containing glycine and glutamic acid is recommended for colorimetric measurement because of better match with blood filtrates. *Glycine Standard.* Dissolve exactly 0.268 g. of pure dry glycine in water and transfer with rinsings to a 500-ml. volumetric flask. Add 35 ml. of N hydro-

filtrate to a test tube graduated at 15 ml. In a similar tube place 5 ml. of amino acid standard solution, containing 0.03 mg. of amino acid nitrogen, and for photometric measurement prepare a blank tube containing 5 ml. of water.<sup>71</sup> Add 1 drop of 0.25 per cent alcoholic phenolphthalein solution to each tube, followed by 0.1 N sodium hydroxide solution drop by drop until a permanent pink color is obtained. Adjust by adding a little water where necessary so that all tubes are at approximately the same volume. To each tube add 1 ml. of borax solution, mix by tapping, and then add 1 ml. of freshly prepared naphthoquinone solution. Mix by tapping, and place the tubes immediately in a boiling water bath. Allow to remain 10 minutes, then remove and place in cold water for 5 minutes. To the cooled contents of each tube add 1 ml. of acid-formaldehyde solution, mix immediately, add 1 ml. of 0.1 N sodium thiosulfate solution, dilute immediately to the 15-ml. mark with water, and mix by inversion. Allow to stand for 10 to 30 minutes before reading in the colorimeter or photometer. For colorimetric measurement, match the unknown against the standard in the usual way. For photometric measurement, transfer the solutions to suitable containers and read in the photometer at 490 m $\mu$ , using the blank solution for setting the photometer to zero density.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.03 \times \frac{100}{0.5} = \text{mg. amino acid nitrogen per 100 ml. blood or plasma}$$

If the unknown has an amino acid nitrogen content outside the range of 4 to 8 mg. per cent, repeat the determination using smaller portions of filtrate or standard as required, made up to 5 ml. with water, and correct the calculations accordingly.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.03 \times \frac{100}{0.5} = \text{mg. amino acid nitrogen per 100 ml. blood or plasma}$$

chloric acid and 1 g. of sodium benzoate. Add water to dissolve and dilute to 500 ml. with water. Mix. *Glutamic Acid Standard.* Dissolve exactly 0.525 g. of pure dry glutamic acid in water, transfer to a 500-ml. volumetric flask, add 35 ml. of N hydrochloric acid and 1 g. of sodium benzoate as above, dilute to 500 ml. with water, and mix. Each of these stock standards contains 0.1 mg. of amino acid nitrogen per ml. They are stable indefinitely. To prepare the *mixed standard*, transfer 3 ml. of both the glycine and glutamic acid standards to a 100-ml. volumetric flask, dilute to the mark with water, and mix. This standard contains 0.03 mg. of amino acid nitrogen in 5 ml. and is usable for one week if kept in the cold.

*0.25 Per Cent Alcoholic Phenolphthalein.* Dissolve 0.25 g. of phenolphthalein in 95 per cent alcohol and dilute to 100 ml.

*0.1 N Sodium Hydroxide.* Dilute 10 ml. of N sodium hydroxide solution to 100 ml. with water and mix.

*Borax Solution.* Dissolve 15 g. of borax (sodium tetraborate, Na<sub>2</sub>B<sub>4</sub>O<sub>7</sub>·10H<sub>2</sub>O) in water and dilute to 1 liter. Stable indefinitely.

*Naphthoquinone Solution.* Dissolve 0.25 g. of  $\beta$ -naphthoquinone-4-sulfonic acid in water and dilute to 50 ml. Prepare immediately before using, and discard remaining solution.

*Acid-Formaldehyde Solution.* Dilute 11.3 ml. of 40 per cent formaldehyde to 1 liter with water. Mix 4 volumes of this solution with 3 volumes of 1.5 N hydrochloric acid and 1 volume of glacial acetic acid. Stable indefinitely.

*0.1 N Sodium Thiosulfate Solution.* This need not be standardized. Dissolve 25 g. of crystalline sodium thiosulfate in water, dilute to 1 liter with water, and mix. Usable indefinitely.

<sup>71</sup> A water blank is valid only if the reagents used in preparing the blood filtrate (tungstate, acid) are substantially ammonia-free.

For the spectrophotometric characteristics of the color obtained in this method, see Frame, Russell, and Wilhelmi (*loc. cit.*). At 490  $m\mu$  and in a 1-cm. cuvette, the density of the standard is approximately 0.400; at 520  $m\mu$ , which may be used with slightly less accuracy, the density is about 25 per cent less. Up to about 15 mg. per cent amino acid nitrogen may therefore be determined accurately under these conditions; for higher levels, repeat the analysis with a smaller portion of filtrate.

**Interpretation.** The amino acid nitrogen content of whole blood as determined by this method ranges from 5 to 8 mg. per cent. A slight increase is noted after the ingestion of protein foods but no significant change is found in fasting. High values have been observed in uremic nephritis although a remarkable constancy is observed in most pathological conditions. Increases have, however, been noted in leukemia and particularly in acute yellow atrophy of the liver. Insulin markedly reduces the amino acid content of blood. Plasma averages around 4 to 5 mg. per cent, with serum slightly higher: according to MacFadyen,<sup>72</sup> this increase is due to release of amino acids during clotting. The concentration of amino nitrogen in corpuscles is about twice that of whole blood. Of naturally occurring interfering substances, glutathione is of chief significance; since this substance is present largely in the corpuscles, interference from this source is minimized if plasma (or an "unlaked" blood filtrate<sup>67</sup>) is taken for analysis. Uric acid at a concentration of 1 mg. per cent gives color equivalent to 0.1 mg. per cent amino acid nitrogen;<sup>69</sup> correction may be necessary on bloods with high uric acid content. The sulfonamides also interfere if present; a free sulfonamide level of 10 mg. per cent being equivalent to 0.8 mg. per cent amino acid nitrogen;<sup>69</sup> correction may also be applied here. Despite these limitations, the method is considered to be reliable and satisfactory for blood analysis.

**Other Methods.** Other colorimetric methods are not as satisfactory as the one described here. Gasometric methods include the classical nitrous acid method of Van Slyke,<sup>73</sup> which is based upon the measurement of nitrogen liberated from  $\alpha$ -amino acids on treatment with nitrous acid; and the gasometric ninhydrin method of Van Slyke and Dillon,<sup>74</sup> in which the carbon dioxide liberated from the carboxyl group of  $\alpha$ -amino acids on boiling with ninhydrin is measured. For description of the ninhydrin method as applied to the determination of the amino acid content of urine, see Chapter 31. Microbiological methods for the determination of individual amino acids are described in Chapter 33.

## DETERMINATION OF GLUCOSE

**Introduction.** The majority of methods for the determination of blood glucose are based upon the ability of glucose in hot alkaline solution to reduce certain metallic ions, of which the cupric and ferricyanide ions are most commonly used. The extent of reduction is then established by colorimetric, titrimetric, or gasometric methods. Methods involving or

<sup>72</sup> MacFadyen: *J. Biol. Chem.*, **145**, 387 (1942).

<sup>73</sup> See Van Slyke and Peters: *Quantitative Clinical Chemistry*, Vol. II (Methods), Baltimore, Williams and Wilkins Co., 1932.

<sup>74</sup> Van Slyke and Dillon: *Proc. Soc. Exptl. Biol. Med.*, **34**, 362 (1936); Van Slyke, Dillon, MacFadyen, and Hamilton: *J. Biol. Chem.*, **141**, 627 (1941). MacFadyen: *loc. cit.*

including yeast fermentation,<sup>75</sup> while undoubtedly the most specific for glucose, are not used routinely. It has long been known that there are reducing substances other than glucose present in blood, and that these may occur in sufficient amount to increase considerably the "apparent" glucose value. The term "saccharoid" has been proposed to designate the non-glucose reducing fraction of blood.<sup>76</sup> The various blood sugar methods differ in their specificity for glucose, and therefore tend to give slightly or even significantly different values for both normal and pathological blood. In using a method, or in interpreting results obtained by it, particularly in the early literature, it is important to know the relationship between the values obtained by the particular method and the "true glucose" values, as well as the values obtained by other and possibly more specific methods. It is also important to know whether the method employs venous or arterial (capillary) blood, since this may influence the interpretation of results (see p. 577). Because of the free diffusibility of glucose between red cells and plasma, distinction between the analysis of whole blood and plasma is relatively unimportant except for methods which include the reduction due to saccharoids, which are found chiefly in the red cells.

**1. Method of Folin and Wu:<sup>77</sup> Principle.** The protein-free blood filtrate is heated with alkaline copper solution, using a special tube to prevent reoxidation. The cuprous oxide formed is treated with a phosphomolybdic acid solution, a blue color being obtained which is compared with that of a standard.

**Procedure.<sup>78</sup> Transfer 2 ml. of the tungstic acid blood filtrate (or 1 ml. plus 1 ml. of water if very high blood sugar values are expected) to a Folin-Wu**

---

<sup>75</sup> See Somogyi: *J. Biol. Chem.*, **78**, 117 (1928); Van Slyke and Hawkins: *ibid.*, **83**, 51 (1929); Holden: *ibid.*, **119**, 347 (1937); Winzler: *Science*, **99**, 327 (1944).

<sup>76</sup> Benedict: *J. Biol. Chem.*, **92**, 141 (1931). According to Fashena (*J. Biol. Chem.*, **100**, 357 (1933); Fashena and Stiff: *ibid.*, **137**, 21 (1941)) the saccharoid fraction of normal human blood is accounted for almost entirely by glutathione and glucuronic acid.

<sup>77</sup> Folin and Wu: *J. Biol. Chem.*, **41**, 367 (1920). Folin (*J. Biol. Chem.*, **67**, 357 (1926); **82**, 83 (1929)) has critically examined and improved this method to obtain a more accurate measure of true sugar and better proportionality between sugar concentration and color intensity. The original Folin-Wu method is here described because it continues to have wide usage, especially in hospital laboratories.

<sup>78</sup> Reagents Required: *Standard Sugar Solutions*. Three standard sugar solutions should be on hand: (a) a stock solution, 1 per cent glucose made up in saturated benzoic acid solution; (b) a solution containing 2 mg. of sugar in 1 ml. (20 ml. of stock solution diluted to 100 ml. with water); (c) solutions containing 0.2 and 0.4 mg. of sugar in 2 ml., made by dilution of (b) with water. The dilute standards are best made up fresh a couple of times a week. Merck's *highest purity* dextrose is satisfactory.

*Alkaline Copper Solution*. Dissolve 40 g. of pure anhydrous sodium carbonate in about 400 ml. of water and transfer to a liter flask. Add 7.5 g. of tartaric acid, and when the latter has dissolved add 4.5 g. of crystallized copper sulfate. Mix and make up to a volume of 1 liter. If the chemicals used are not pure a sediment of cuprous oxide may form in the course of one or two weeks. If this should happen, remove the clear supernatant reagent with a siphon, or filter through a good quality filter paper. The reagent seems to keep indefinitely. To test for the absence of cuprous copper in the solution, transfer 2 ml. to a test tube and add 2 ml. of the molybdate phosphate solution; the deep blue color of the copper should almost completely vanish. In order to forestall improper use of this reagent attention should be called to the fact that it contains extremely little alkali, 2 ml. by titration (using the fading of the blue copper tartrate color as indicator) requiring only about 1.4 ml. of normal acid.

*Phosphomolybdic Acid Solution*. To 35 g. of molybdic acid and 5 g. of sodium tungstate, add 200 ml. of 10 per cent sodium hydroxide and 200 ml. of water. Boil vigorously for 20

sugar tube graduated at 25 ml. (Fig. 151) and to other similar tubes add 2 ml. of standard sugar solutions containing 0.2 and 0.4 mg. respectively of glucose. To each tube add 2 ml. of the alkaline copper solution. The surface of the mixtures must now have reached the constricted part of the tube. Transfer the tubes to a rapidly boiling water bath and heat for 8 minutes. Cool in running water without shaking. To each tube add 2 ml. of phosphomolybdic acid reagent. After about 1 minute dilute to the mark with water and mix. It is essential that adequate attention be given to this mixing because the greater part of the blue color is formed in the bulb of the tube. Compare in a colorimeter using the standard which most nearly matches the unknown. For photometric measurement, transfer the solutions to suitable containers and determine the densities at 420 m $\mu$ , setting the photometer to zero density with a blank obtained by treating 2 ml. of water with alkaline copper reagent, heating, etc., just as in the analysis of the blood filtrate.

CALCULATION. *For colorimetric measurement*, use the standard which most closely matches the unknown, and calculate as follows:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{mg. glucose in standard} \times \frac{100}{0.2} \\ = \text{mg. glucose per 100 ml. blood}$$

Unless the readings of the standard and unknown are within a few millimeters of each other, results obtained by this calculation are somewhat incorrect because the color is not strictly proportional to the concentration of glucose. Correction of observed blood sugar values<sup>79</sup> may be of importance when the values are near the critical levels corresponding to hypoglycemia and to the threshold range. Instead of applying corrections it may be advisable to employ, in place of the usual standards, standards containing 0.1 and 0.3 mg. of glucose in 2 ml. (corresponding to blood sugar values of 50 and 150 mg. per 100 ml., respectively) or to dilute to an approximate color match (using the graduated sugar tubes of Rothberg and Evans)<sup>80</sup> prior to matching in the colorimeter.

*For photometric measurement*, only one standard and a blank are required, and the calculation is as follows:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{mg. glucose in standard} \times \frac{100}{0.2} \\ = \text{mg. glucose per 100 ml. blood}$$

At 420 m $\mu$  and in a 1-cm. cuvette, the density of the standard containing 0.4 mg. of glucose, corresponding to 200 mg. per cent of blood glucose, is approximately 0.300 (Fig. 152). Satisfactory agreement with Beer's law is found under these conditions up

to 40 minutes so as to remove nearly the whole of the ammonia present in the molybdic acid. Cool, dilute to about 350 ml. and add 125 ml. of concentrated (85 per cent) phosphoric acid. Dilute to 500 ml.

<sup>79</sup> Oser and Karr (*J. Biol. Chem.*, 67, 319 (1926)) have published tables and curves correcting for the deviation from Beer's law.

<sup>80</sup> Rothberg and Evans: *J. Biol. Chem.*, 58, 443 (1923).

FIG. 151. FOLIN-WU SUGAR TUBE.

to about 400 mg. per cent blood glucose. For higher values, or with deeper cuvettes, carry out the analysis using less filtrate plus water to 2 ml., and correct the calculations accordingly.

FIG. 152. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED IN FOLIN-WU BLOOD SUGAR METHOD.

For standards containing (a) 0.2 mg. and (b) 0.4 mg. glucose. Solution depth, 1 cm.

**Interpretation.** The normal range of fasting venous blood sugar values by this method is 90 to 120 mg. per 100 ml. of whole blood. This range is undoubtedly “enhanced” to the extent of possibly 20 to 30 mg. per cent by the effect of non-glucose reducing substances (saccharoids), but the saccharoid fraction appears to be relatively constant and therefore its presence does not influence unduly the interpretation of variations in blood sugar level as obtained by this procedure. Most of the early data in the American literature on blood sugar content were obtained by this method, but it is gradually being superseded by the more specific methods described subsequently.

In mild diabetes values of 140 to 300 mg. per cent are obtained, and in severe diabetes values up to 1200 mg. per cent have been noted. Hyperglycemia is also observed in severe nephritis, pancreatic disease, hyperthyroidism, and certain hepatic disorders. Experimentally, the administration of adrenaline and the induction of ether anesthesia lead to elevated blood sugar values. Low blood sugar values are found after the administration of insulin, in such hypoendocrine disturbances as Addison’s disease, hypopituitarism, cretinism, and myxedema, and in the clinical condition known as hyperinsulinism. For carbohydrate tolerance test, see p. 579.

**2. Method of Benedict:**<sup>81</sup> **Principle.** The protein-free filtrate is heated with an alkaline copper reagent containing tartrate, alanine, and bisulfite. The reduced copper is determined colorimetrically after treatment with phosphomolybdic acid. The alkaline copper reagent used here is practically unaffected by the nonsugar reducing materials present in blood, hence the method gives values distinctly lower than with the Folin-Wu method, and presumably nearer the true glucose content. The reagent is also adapted to the determination of the nonsugar reducing value of blood (see original paper).

<sup>81</sup> Benedict: *J. Biol. Chem.*, **92**, 141 (1931).

**Procedure.**<sup>82</sup> Place 2 ml. of 1:10 protein-free filtrate<sup>83</sup> in a Folin-Wu sugar tube, and in a second similar tube place 2 ml. of standard glucose solution. To each tube add 2 ml. of the copper reagent containing bisulfite. Mix by lateral shaking, and place in a vigorously boiling water bath for 6 minutes. Cool by placing in cold water for 1 to 2 minutes (avoid shaking at this stage). To each tube add 2 ml. of color reagent, mix by vigorous lateral shaking, and after about 1 minute dilute with water to the 25-ml. mark. Mix the contents thoroughly by repeated inversion, allow to stand at least 10 minutes, and read in the colorimeter or photometer within the next 30 minutes or so. For colorimetric measurement, compare against the standard in the usual way. For photometric measurement, transfer portions of the solutions to suitable containers and determine the densities in the photometer under the same conditions as described for the Folin-Wu method, p. 569.

**CALCULATION.** Same as for Folin-Wu method.

This procedure gives better proportionality between color and concentration than the Folin-Wu method. A standard glucose solution containing 0.2 mg. of glucose, equivalent to 100 mg. per cent blood sugar, is therefore suitable in colorimetric comparison for values up to 200 mg. per cent blood sugar. For higher levels, use a stronger standard or less filtrate plus water to 2 ml. In photometric measurement, agreement with Beer's law is excellent up to 500 mg. per cent blood sugar, at 420  $m\mu$ , and in a 1-cm. cuvette. For higher values, or with a deeper cuvette, carry out the analysis using less filtrate plus water to 2 ml., and correct the calculations accordingly.

**Interpretation.** Normal values on whole blood by this method range from 70 to 100 mg. per cent blood glucose. The interpretation of variation from the normal range is similar to that already presented in connection with the Folin-Wu method.

**3. Somogyi-Shaffer-Hartmann Method:**<sup>84</sup> **Principle.** Hemolyzed blood is deproteinized with zinc hydroxide, giving a filtrate containing practically no reducing substances other than sugar. The sugar is estimated by iodometric titration of reduced

---

<sup>82</sup> Reagents Required: *Copper Reagent.* Dissolve 15 g. of anhydrous sodium carbonate, 3 g. of alanine, and 2 g. of Rochelle salt in about 250 ml. of distilled water. Dissolve 3 g. of crystalline copper sulfate in about 100 ml. of distilled water and add this solution with stirring to the carbonate-alanine-tartrate solution. Dilute to 500 ml. and mix. Keep in a cool place. This reagent will keep ready mixed from 4 to 6 weeks. If, after several weeks, there may be a slight growth of mold in the solution, it may be removed at any time by pouring the solution through a loose plug of absorbent cotton in a funnel, leaving the efficiency of the reagent unaffected.

*1 Per Cent Sodium Bisulfite Solution.* Kept in a 100-ml. dropping bottle. The solution should be prepared fresh about once a month.

*Copper Reagent Containing Bisulfite.* Measure into a cylinder a volume of the copper reagent which will be used up in one or two days, and add 1 drop of the bisulfite solution for each ml. of copper reagent, or 1 ml. of bisulfite for each 20 ml. of reagent. Mix. Do not use after the second day.

*Color Reagent.* To 150 g. of pure molybdic acid and 75 g. of anhydrous  $\text{Na}_2\text{CO}_3$  in a large Erlenmeyer flask, add 500 ml. of water in small portions while shaking. Heat to boiling. Filter. Wash residue on filter with hot water until filtrate plus washings equal 600 ml. Add 300 ml. of 85 per cent  $\text{H}_3\text{PO}_4$ , cool, and dilute to 1 liter.

*Standard Glucose Solution.* See footnote 78, p. 568.

<sup>83</sup> Benedict uses a tungstomolybdate filtrate (Benedict: *J. Biol. Chem.*, **92**, 135 (1931)). A Folin-Wu filtrate may also be used.

<sup>84</sup> Somogyi: *J. Biol. Chem.*, **86**, 655 (1930); **70**, 599 (1926). Urea, creatinine, and creatine may also be determined in the zinc filtrate but only traces of uric acid are found. Lower but significant values for nonprotein nitrogen may be obtained (*J. Biol. Chem.*, **87**, 339 (1930)). For an improved procedure, suitable for colorimetric as well as titrimetric determination, see Somogyi: *J. Biol. Chem.*, **160**, 61, 69 (1945).

copper. Precipitation of the protein with copper salts is just as satisfactory in the case of whole blood and is better for plasma or serum.<sup>85</sup>

**Procedure.** (a) DEPROTEINIZATION. Take 1 volume of blood with 7 volumes of water. Add 1 volume of 10 per cent solution of  $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ . Mix. Add with continuous shaking 1 volume of 0.5 N NaOH. Stopper the flask, shake well, and filter after a few minutes through dry filter paper. For accurate work measure the blood with an Ostwald pipet calibrated "to contain" and rinse with the laking water. For serum or plasma dilute with 8 volumes of water and add 0.5 volume of each of the reagents. Another procedure for whole blood is to add 8 volumes of an acid zinc solution (12.5 g. of  $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$  and 125 ml. of 0.25 N  $\text{H}_2\text{SO}_4$  with water to make 1 liter) and 1 volume of 0.75 N NaOH. Shake vigorously and filter after a few minutes. 50 ml. of the acid zinc solution should require 6.7 to 6.8 ml. of 0.75 N NaOH to give a permanent pink with phenolphthalein. Determine sugar as below. For microtechnique introduce into a test tube or 25-ml. Erlenmeyer flask 5.8 ml. of water, add 0.2 ml. of blood from an accurate capillary pipet, rinsing several times with the laking water. Mix. Add 1 ml. of 1.8 per cent  $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ . Mix. Add with continuous shaking 1 ml. of 0.1 N NaOH.<sup>86</sup> Stopper, shake well, and filter after a few minutes through a dry thin paper (Schleicher and Schüll No. 597, 70 mm.). Use 5 ml. of filtrate equivalent to 0.125 ml. of blood. Determine sugar by procedure described.

(b) DETERMINATION OF SUGAR. Measure 5 ml. of the copper reagent<sup>87</sup> into a large test tube (25 × 250 mm.) and add 5 ml. of the sugar solution<sup>88</sup> containing not less than 0.1 nor more than 2.0 mg. of glucose. Shake gently to mix, cover the tube with a small funnel, bottle cap, or glass bulb, and keep in a boiling water bath for 15 minutes. Cool (avoid shaking) by placing in a shallow dish of water until the temperature falls to 35° to 40° C. (not below 30°). Add 1 ml. of 5 N  $\text{H}_2\text{SO}_4$  (or equivalent amount) and see that all  $\text{Cu}_2\text{O}$  is promptly dissolved. Avoid reoxidation of reduced copper or loss of iodine by too vigorous agitation. After about 2 minutes titrate with 0.005 N sodium thiosulfate, using starch as an indicator toward the end of the titration. Run a blank on 5 ml. of reagent after heating with an equal volume of water.

**CALCULATION.** From the blank titration subtract the titration of the unknown. This gives ml. of thiosulfate required. For the glucose equivalent consult the following table, which applies to the usual 1:10 dilutions of blood. For other cases the actual amount of glucose in the 5 ml. of solution used for the determination is obtained by dividing the value in the table by 200.

---

<sup>85</sup> Somogyi: *J. Biol. Chem.*, **90**, 725 (1931). Take 1 volume of blood in 7 volumes of water. Add 1 volume of 7 per cent  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  and mix. Then add, with continuous shaking, 1 volume of 10 per cent  $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$ . Stopper the flask. Shake well. Filter through dry filter paper after a few minutes. For plasma or serum use the same procedure but use 5 per cent copper sulfate and 6 per cent sodium tungstate solutions.

<sup>86</sup> 10 ml. of the zinc sulfate solution diluted with 60 ml. of water and slowly titrated with the NaOH should require 12 to 12.2 ml. for a permanent pink with phenolphthalein.

<sup>87</sup> *Copper Reagent.* Dissolve 12 g. of Rochelle salt, 20 g. of sodium carbonate (anhydrous), and 25 g. of sodium bicarbonate in about 500 ml. of water. Into this pour with stirring 6.5 g. of copper sulfate (crystalline) dissolved in about 100 ml. of water. Dissolve 10 g. of potassium iodide, 0.80 g. (weighed to cg.) of potassium iodate, and 18 g. of potassium oxalate in about 200 ml. of water. Add to the main solution and dilute to 1 liter.

*Thiosulfate.* For preparation of 0.1 N solution see Appendix. Dilute this every day or two as needed to 0.005 N.

<sup>88</sup> Strongly acid sugar solutions must be neutralized to phenol red. For above filtrates or tungstic acid filtrates this is not necessary.

**Interpretation.** Normal values by this method range from 70 to 100 mg. per cent and are presumably very close to the true glucose values. The specificity for glucose appears to reside in the method of deproteinization, since filtrates prepared as described may be analyzed for glucose by the Folin-Wu or Benedict colorimetric methods to give results substantially identical with those obtained by the Shaffer-Hartmann iodometric titration. For the principle of the Shaffer-Hartmann procedure, see Chapter 31.

**4. Nelson-Somogyi Method:<sup>89</sup> Principle.** Blood is deproteinized by a zinc hydroxide-barium sulfate procedure which gives a filtrate containing practically no reducing substances other than glucose. The zinc-barium filtrate is heated with an alkaline copper reagent and then treated with a special arsenomolybdate color reagent. The color developed is compared with that obtained from a known amount of glucose.

**Procedure.<sup>90</sup>** (a) DEPROTEINIZATION. Place 1 ml. of blood in a 50-ml. flask. Add 9.5 ml. of barium hydroxide solution, mixing by rotation. Add 9.5 ml. of

<sup>89</sup> Nelson: *J. Biol. Chem.*, **153**, 375 (1944); Somogyi: *J. Biol. Chem.*, **160**, 62 (1945). Adapted by permission from the official procedures of the American Association of Clinical Chemists.

<sup>90</sup> Reagents Required: *Barium Hydroxide Solution*. Dissolve 90 g. of Ba(OH)<sub>2</sub>·8H<sub>2</sub>O in distilled water and dilute to 2000 ml. in a graduated cylinder. Filter if cloudy. Store in well-

zinc sulfate solution, mixing by rotation. Shake vigorously and filter on a dry filter paper, collecting the filtrate in a dry flask.

(b) DETERMINATION OF GLUCOSE. Measure 0.5 ml. of the barium-zinc filtrate into a test tube calibrated at 10 ml. Add 1 ml. of alkaline copper reagent, mix by tapping, cover the top of the tube with a marble, and place upright in a boiling water bath for 20 minutes. Cool by placing the tube in water at room temperature for 1 minute. Add 1 ml. of arsenomolybdate color reagent, mixing by tapping; then dilute to 10 ml. with distilled water. Mix by inversion. Compare in a colorimeter against a simultaneously prepared standard obtained by treating 0.5 ml. of standard glucose solution (see footnote 90) exactly as described for the blood filtrate. For photometric measurement, prepare a blank by carrying out the procedure as described on 0.5 ml. of water. Set the photometer to zero density with the blank, and measure the optical densities of standard and unknown at 540  $m\mu$ .

CALCULATION. For colorimetric measurement, calculate as follows:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{mg. glucose in standard} \times \frac{100}{0.025} \\ = \text{mg. glucose per 100 ml. blood}$$

It is convenient to set up three standards, covering low, normal, and high values of blood glucose, as follows: I, containing 0.0125 mg. glucose, for low values; II, containing 0.025 mg. glucose, for normal values; III, containing 0.050 mg. glucose, for high values. The unknown is then compared against the standard it most closely

stoppered containers filled to capacity.

*Zinc Sulfate Solution.* Dissolve 100 g. of  $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$  in distilled water, dilute to 2000 ml. in a graduated cylinder, and mix. Stable indefinitely.

It is most important that these two solutions exactly neutralize each other. Check by measuring 10 ml. of zinc sulfate solution into a flask, diluting with about 50 ml. of distilled water, add 4 drops of phenolphthalein solution, and titrate with the barium hydroxide solution, slowly and with constant shaking, until 1 drop of alkali turns the mixture pink. If it requires more or less than 10.00 ml.  $\pm$  0.05 ml. of barium hydroxide, dilute one or the other solution as required and check again. Continue until the two solutions are exactly equivalent. Protect the barium hydroxide solution in the dispensing bottle with a soda-lime tube in the stopper, and test both solutions occasionally by making a trial filtrate on blood. Satisfactory solutions will give a clear filtrate which filters rapidly and shows little tendency to foam.

*Alkaline Copper Reagent: Solution A.* Dissolve 50 g. of anhydrous sodium carbonate, 50 g. of Rochelle salt, 40 g. of sodium bicarbonate, and 400 g. of anhydrous sodium sulfate in about 1600 ml. of distilled water, and dilute to 2 liters. Mix and filter if not clear. Store at room temperature. If a sediment forms in a few days, filter again. *Solution B.* Dissolve 150 g. of  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  in distilled water and dilute to 1 liter. Add 0.5 ml. of concentrated sulfuric acid, and mix. *Alkaline Copper Reagent.* On the day it is to be used, place 4 ml. of Solution B in a 100-ml. graduated cylinder, dilute to 100 ml. with Solution A, and mix.

*Arsenomolybdate Color Reagent.* Dissolve 100 g. of ammonium molybdate in 1800 ml. of distilled water. Add 84 ml. of concentrated sulfuric acid, with stirring. Dissolve 12 g. of disodium orthoarsenate ( $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$ ) in 100 ml. of distilled water, and add it with stirring to the acidified molybdate solution. Place the mixture in an incubator at 37° C. for 1 to 2 days. Store in a glass-stoppered brown glass bottle. This solution should be stable indefinitely.

*Standard Glucose Solutions.* Prepare a stock standard by dissolving exactly 1.00 g. of highest purity anhydrous glucose in about 10 to 15 ml. of 0.2 per cent benzoic acid solution, transferring quantitatively to a 100-ml. volumetric flask, diluting to the mark with the benzoic acid solution, and mixing. This solution is stable indefinitely, and contains 10 mg. of glucose per ml. Standard I (0.0125 mg. glucose per 0.5 ml.) is prepared by diluting 0.5 ml. of the stock standard to 200 ml. with 0.2 per cent benzoic acid solution and mixing. For Standard II (0.025 mg. glucose per 0.5 ml.) dilute 1.0 ml. of stock standard to 200 ml. as described for Standard I, and for Standard III (0.050 mg. glucose per 0.5 ml.) dilute 2.0 ml. of stock standard to 200 ml. These dilute solutions in 0.2 per cent benzoic acid solution keep indefinitely at room temperature.

matches. The calculation can be simplified as follows:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times f = \text{mg. glucose per 100 ml. blood}$$

where  $f$  is a factor with the following values: for standard I, 50; for standard II, 100; for standard III, 200.

For photometric measurement, the calculation is as follows:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{mg. glucose in standard} \times \frac{100}{0.025} = \text{mg. glucose per 100 ml. blood}$$

A standard containing 0.025 mg. of glucose is satisfactory for blood samples containing up to 350 mg. per cent blood sugar. With this standard the calculation simplifies to:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 100 = \text{mg. glucose per 100 ml. blood}$$

For samples containing more than 350 mg. per cent blood sugar, repeat the analysis using a smaller aliquot of filtrate plus water to make 0.5 ml., and correct the calculations accordingly. The colors obtained by this method are said to be stable for more than 24 hours.

**Interpretation.** Normal values on fasting venous blood by this method range between 65 and 110 mg. per 100 ml. of whole blood, with an average value of 85 mg. per 100 ml. The interpretation of variation from the normal range is similar to that already presented in connection with the Folin-Wu method.

#### 5. Micromethod for Glucose in 0.1 Ml. of Blood (Folin and Malmros):<sup>91</sup>

**Principle.** The sugar is oxidized with alkaline potassium ferricyanide, and the ferrocyanide produced is measured colorimetrically or photometrically after conversion to Prussian blue.

**Procedure.** With an accurate 0.1-ml. pipet<sup>92</sup> collect 0.1 ml. of blood and transfer it to 10 ml. of dilute tungstic acid<sup>93</sup> in a centrifuge tube. Stir well and

<sup>91</sup> Folin and Malmros: *J. Biol. Chem.*, **83**, 115 (1929); Folin: *J. Biol. Chem.*, **77**, 421 (1928). See also Horvath and Knehr: *J. Biol. Chem.*, **140**, 869 (1941). For a method based upon titration of the ferrocyanide formed using ceric sulfate, see Miller and Van Slyke: *J. Biol. Chem.*, **114**, 583 (1936); MacFadyen and Van Slyke: *ibid.*, **149**, 527 (1943). See also the Hawkins and Van Slyke method, Chapter 31.

<sup>92</sup> A capillary pipet about 7 cm. in length per 0.1 ml., calibrated "to contain," using mercury (0.1 ml. weighs 1.355 g.). Sold by dealers in laboratory supplies.

<sup>93</sup> *Dilute Tungstic Acid Solution.* Transfer 20 ml. of 10 per cent sodium tungstate to a liter volumetric flask. Dilute to about 800 ml. Add with shaking 20 ml. of  $\frac{2}{3}$  N sulfuric acid and dilute to volume.

*Potassium Ferricyanide Solution.* Dissolve 2 g. of c.p. potassium ferricyanide in distilled water and dilute to a volume of 500 ml. Keep the major part of the solution in a brown bottle in a dark closet. Keep the reagent in daily use also in a brown bottle.

*Sodium Cyanide-Carbonate Solution.* Transfer 8 g. of anhydrous sodium carbonate to a 500 ml. volumetric flask. Add 40 to 50 ml. of water and shake to promote rapid solution. With a cylinder, add 150 ml. of freshly prepared 1 per cent sodium cyanide solution, dilute to volume, and mix.

*Ferric Iron Solution.* Fill a liter cylinder with water. Suspend on a copper wire screen, just below the surface, 20 g. of soluble gum ghatti, and leave overnight (18 hours). Remove the screen, and strain the liquid through a double layer of a clean towel. Add to this extract a solution of 5 g. of anhydrous ferric sulfate in 75 ml. of 85 per cent phosphoric acid plus 100 ml. of water. Add to the mixture, a little at a time, about 15 ml. of 1 per cent potassium permanganate solution to destroy certain reducing materials present in gum ghatti. The

centrifuge. Transfer 4 ml. of the water-clear supernatant fluid to a test tube graduated (with a ring going all around) at 25 ml. Transfer 4 ml. of the standard sugar solution to another similar tube. To each tube add 2 ml. of the 0.4 per cent potassium ferricyanide solution and 1 ml. of the cyanide-carbonate solution. Heat immediately in boiling water for 8 minutes<sup>94</sup> and cool in running water for 1 to 2 minutes. Add 5 ml. of the ferric iron solution and mix. Let stand for 1 to 2 minutes and then dilute with water nearly, but not quite, to the 25-ml. mark. Add 2 drops of alcohol to cut the foam and dilute to the mark. Mix. Allow to stand 10 minutes and read within the next 30 minutes.

For colorimetric comparison, half fill the colorimeter cups with the green-colored standard, set the two plungers at a height of 20 mm., and cover the opening of the light box with the picric acid light filter.<sup>95</sup> Adjust the position of the colorimeter and of the mirror glass reflector until the two fields look exactly alike. The adjustment is easier if the colorimeter is kept on a piece of plate glass polished on one side and rough on the other. Rinse one colorimeter cup and plunger with the unknown solution and pour the unknown into the cup to a suitable height. Compare in the usual way.

For photometric measurement, transfer the solutions to suitable containers and determine the densities in a photometer at 520 m $\mu$ . Set the photometer to zero density with water alone, rather than use a blank (see below).

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.04 \times \frac{10}{4.0} \times \frac{100}{0.1} = \text{mg. glucose per 100 ml. blood}$$

The proportionality between color and concentration is excellent in this method, so that readings between 5 and 40 mm. may be accepted, with the standard at 20 mm., if perfect equality as to light and color is obtained. If the blood glucose concentration is over 400 mg. per cent, repeat with 2 ml. of filtrate plus 2 ml. of water, and multiply the results by 2.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.04 \times \frac{10}{4.0} \times \frac{100}{0.1} = \text{mg. glucose per 100 ml. blood}$$

At the wavelength specified, and in a 1-cm. cuvette, the standard corresponding to

slight turbidity of the solution will disappear completely, if kept at 37° C. for a few days. The use of Duponol, a synthetic detergent, has been recommended in place of gum ghatti (Klendshoj and Hubbard: *J. Lab. Clin. Med.*, **25**, 1102 (1939–1940); Horvath and Knehr: *loc. cit.*).

*Standard Glucose Solution.* The working standard contains 0.01 mg. of glucose per ml. (see footnote 78, p. 568).

<sup>94</sup> Heating for 20 minutes instead of 8 minutes, to ensure complete oxidation of glucose, has been recommended by Jourdonais: *J. Lab. Clin. Med.*, **23**, 847 (1937–1938); and by Horvath and Knehr: *loc. cit.*

<sup>95</sup> Dissolve 5 g. of picric acid in 100 ml. of methyl alcohol and add 5 ml. of 10 per cent NaOH. Place a pack of 8 to 10 heavy absorbent filter papers (Schleicher and Schüll, No. 604 is good) on a level and smooth mat of newspapers. Pour the acid picrate solution over the filters until the papers are saturated and an excess of solution filters through. Allow to dry. When perfectly dry, pour over the pack an excess of a 3 per cent solution of paraffin in benzine. Allow to dry. All papers should be evenly stained. Cover the light-box window of the colorimeter lamp with stained paper. Test the efficiency by comparing water and 0.2 per cent potassium ferricyanide solution, both set at 20 mm. Adjust the colorimeter so that the two fields look alike. If the filter is inadequate, equality of the fields cannot be obtained. A strong light is necessary. A filter in the form of a glass disk to be put on top of the ocular may be obtained from the Klett Manufacturing Co., New York. See Tauber: *J. Lab. Clin. Med.*, **15**, 766 (1930).

100 mg. per cent blood glucose has a density of about 0.250, permitting accurate measurement up to about 400 mg. per cent blood glucose. For higher values, or with deeper cuvettes, use 2 ml. of filtrate plus 2 ml. of water in the analysis, and multiply the results by 2. With well-prepared reagents, the blank should have a density of less than one-tenth that of the standard given; in the presence of a blood filtrate the blank density is even less, and better agreement with Beer's law is noted if the blank is neglected and the photometer set to zero density with water alone as described.<sup>96</sup>

**Interpretation.** Normal values by this method range from 75 to 105 mg. per cent blood glucose. It must be noted that, if fingertip blood is used, this type of blood is essentially arterial, and resembles venous blood only in the fasting state. Thus during absorption or in a glucose tolerance test, higher glucose values will be obtained on fingertip blood than for venous blood, although the reverse may obtain in severe diabetes. For further interpretation, see p. 570.

**6. Determination of Sugar (Method of Hagedorn and Jensen):<sup>97</sup> Principle.**

The blood protein is precipitated with zinc hydroxide. The filtrate is heated with potassium ferricyanide solution and the amount of ferricyanide reduced is determined by adding an iodide solution and titrating the iodine set free with sodium thiosulfate. The principal reaction is  $2\text{H}_3\text{Fe}(\text{CN})_6 + 2\text{HI} = 2\text{H}_4\text{Fe}(\text{CN})_6 + \text{I}_2$ . The reversal of the reduction reaction is prevented by precipitation of the ferrocyanide formed as a zinc salt.

**Procedure.<sup>98</sup>** Into a test tube (15 × 150 mm.) pipet 1 ml. of 0.1 N NaOH and 5 ml. 0.45 per cent zinc sulfate solution. A gelatinous precipitate of zinc hydroxide forms. 0.1 ml. of blood from a capillary pipet<sup>99</sup> is introduced, the

<sup>96</sup> Unpublished results of Summerson and Robinson.

<sup>97</sup> Hagedorn and Jensen: *Biochem. Z.*, **135**, 46 (1923) and **137**, 92 (1923). For critical studies of this method, with suggested improvements, see Folin and Malmros: *J. Biol. Chem.*, **83**, 121 (1929); Kramer and Steiner: *Biochem. J.*, **25**, 161 (1931).

<sup>98</sup> Reagents Required: *For Protein Precipitation:* 0.1 N NaOH.—Zinc sulfate 0.45 per cent. These solutions are best prepared every eight days by dilution of 2 N NaOH and a zinc sulfate solution containing 45 g. of the salt in 100 ml. of solution. *For Sugar Determination:* Potassium ferricyanide 1.65 g. and sodium carbonate (fused) 10.6 g. in 1000 ml. of water. Protect from light. Iodide-sulfate-chloride solutions: KI, 5 g., zinc sulfate, 10 g., NaCl, 50 g., water to make 200 ml. It is best to prepare the solution without iodide and add the latter to portions of the solution as required. Free iodine can be almost completely removed by filtering through thick paper. The blank will take care of smaller errors. Acetic acid solution: 3 ml. of acetic acid (iron-free) with water to make 100 ml. Starch solution: 1 g. of soluble starch dissolved in 100 ml. of saturated NaCl solution. Sodium thiosulfate solution: 0.7 g. sodium thiosulfate in 500 ml. of water. 0.005 N Potassium iodate: This solution is permanent and is used to check the thiosulfate and ferricyanide solutions which keep less well. It alone need therefore be prepared very accurately. Dissolve 0.3566 g. potassium iodate (water-free) in water to make 2000 ml.

Chemicals of highest purity must be used. Sodium carbonate is best recrystallized and fused in platinum. Acetic acid should be tested for iron, as should also the zinc sulfate, sodium chloride, and potassium iodide. The iodide should also be tested for iodate. Ordinary quantities of the mixed solutions will then give no test for iodine with starch but will give a test if 0.01 ml. of ferricyanide is added. Potassium ferricyanide is prepared by washing crystals of the ordinary product with water, dissolving in water with heat, and filtering the boiling solution through paper previously carefully washed with boiling water, into an evaporating dish set in ice-cold water. The fine crystals are filtered off with suction on another washed paper and again recrystallized. Dry at 50° C. Keep away from sunlight during course of preparation.

<sup>99</sup> The length of the 0.1 ml. pipet from the tip to the mark should be about 10 to 12 cm. and over-all length about 20 cm. Calibrate as follows: With the pipet measure out 0.1 ml. of 0.1 N potassium iodate solution into 10 ml. of water. Add acid and KI solution in the usual way and titrate with 0.02 N thiosulfate. Some of the same iodate solution is then diluted to 0.02 N and exactly 2.0 ml. of this in 10 ml. of water titrated with the same thio-

pipet being washed out twice with the mixture and blown empty. Put in a boiling water bath for 3 minutes. Filter on a funnel of 3 to 4 cm. diameter, prepared with a small filter of washed, moistened, not tightly pressed cotton, into a test tube (30 × 90 mm.). Wash the funnel and filter with two 3-ml. portions of water. Add 2 ml. of alkaline potassium ferricyanide solution and heat in a boiling water bath for 15 minutes. Cool and add 3 ml. of the iodide-sulfate solution and 2 ml. of 3 per cent acetic acid solution. Titrate with 0.005 N sodium thiosulfate, using as an indicator 2 drops of 1 per cent solution of soluble starch in saturated sodium chloride solution.

CALCULATION. Determine the blank obtained by carrying through the whole determination but without the addition of blood.<sup>100</sup> Multiply *A* (the thiosulfate buret reading) by the factor for the thiosulfate (2.00/ml. thiosulfate required for 2 ml. 0.005 N iodate). Express this value (*B*) for unknown and for blank as mg. glucose by consulting the table which follows. Subtract the glucose value of the blank from the glucose value of the unknown. The difference is mg. glucose in 0.1 ml. of blood. Or calculate as follows:  $2.00 - B = x$  (ml. 0.005 N ferricyanide reduced). 2.00 ml. of ferricyanide are reduced by 0.385 mg. of glucose. Therefore mg. per cent glucose =  $0.385 \times \frac{x}{2.0} \times 1000$ .

**Interpretation.** Similar to previous method.

## 7. Manometric Methods for Reducing Sugars.<sup>101</sup> See original papers.

sulfate as before. The two titrations should agree within experimental error (about 0.5 per cent) if the pipet is accurate.

<sup>100</sup> Acetone and β-hydroxybutyric acid do not reduce the reagent. One mg. of uric acid gives a reduction equal to that of 0.53 mg. of glucose, and 1 mg. of creatinine a reduction equal to 0.47 mg. of glucose.

<sup>101</sup> Van Slyke and Hawkins: *J. Biol. Chem.*, **79**, 739 (1928); **83**, 51 (1929).

## CARBOHYDRATE TOLERANCE TEST

**Principle.** Blood sugar is determined at hourly periods following the ingestion of 1 g. of glucose per kilogram of body weight. Urinary sugar for the 24-hour period following the ingestion of the glucose is also determined.

**Procedure.** The first thing in the morning, collect a specimen of urine and one of blood to serve as controls. Then give the patient 1 g. of glucose per kilogram of body weight. The glucose may be given in 50 per cent solution. Collect three or four specimens of blood at hourly intervals and analyze for sugar. Following the taking of glucose collect a 24-hour specimen of urine and determine its sugar content. Brill<sup>102</sup> and others have proposed the use of a test breakfast instead of the glucose meal.

**Interpretation.** In normal individuals, blood sugar rises from the normal value of about 100 mg. to about 150 mg. per 100 ml. at the end of the first hour, and returns to normal by the end of the second hourly period. In pathological conditions, the curve does not follow the normal course. Hyperthyroidism, diabetes mellitus, and nephritis show much greater values, depending on the severity of the disease, and the return to normal is delayed for three hours or more. The higher sugar concentration in the blood during the test may or may not be accompanied by glycuressis, depending upon the "threshold point" of the kidney. In diabetes the threshold point is usually, and sometimes markedly, increased above its normal range of 160 to 180 mg. per 100 ml. In hypoendocrine conditions, in which the blood sugar is low ordinarily, the curve of blood sugar during a tolerance test is quite flat. Wherever possible, it is better practice to obtain quarter-hour specimens of blood, during the first hour. This provides more information concerning the general nature of the curve and the height of the peak. John<sup>103</sup> believes that a diagnosis of diabetes is justified if the curve remains high after three hours, irrespective of the height to which it has risen. Petty and Stoner<sup>104</sup> on the other hand regard the criterion as a rise above 180 mg. They base their claim on simultaneous determinations of respiratory quotients, which show very slight rise in diabetics, but follow the sugar curves in normal individuals and in renal glycosurics. In nondiabetics the peak of the curve is usually between one-half and one hour, while in diabetics it is nearer two hours.

It has been shown by Foster<sup>105</sup> that carbohydrate tolerance tests conducted on finger blood, which is practically arterial, give higher and sharper curves than tests of venous blood collected simultaneously. It appears that some of the glucose of arterial blood is removed and oxidized or stored as glycogen by the tissues. The various mechanisms for glucose utilization appear to be stimulated to overactivity, since the blood sugar

curve frequently falls below its initial level. For further discussion of the application of sugar tolerance tests, consult papers by Hamman and Hirschman, Hubbard and Wright, Bailey, Williams and Humphreys, Allen, Stillman and Fitz, Rabinowitch, Macleod, Foster, and du Vigneaud and Karr. (See references in footnote 105.)

## DETERMINATION OF CHOLESTEROL

**Introduction.** The cholesterol of blood is present in the form of both free cholesterol and cholesterol esters. In the plasma both free and esterified cholesterol is found; in the red cells only the free form appears to be present. Plasma is preferred to whole blood for analysis, since pathological variations in the amount and in the distribution between free and ester forms occur largely in the plasma fraction. Free cholesterol is best determined by precipitation and isolation as the insoluble digitonide; the precipitate may be weighed, or treated with a cholesterol color reaction, or otherwise determined. Total cholesterol is most accurately determined in a colorimetric procedure after preliminary saponification to liberate ester cholesterol from combination, since free cholesterol and ester cholesterol may give different color intensities per unit amount of cholesterol present. Many methods which do not involve saponification have, however, been proposed, as discussed below.

**1. Method of Schoenheimer and Sperry:<sup>106</sup> Principle.** An acetone-alcohol mixture is used to precipitate the proteins and extract the cholesterol and cholesterol esters from the sample of whole blood or (preferably) plasma or serum. The cholesterol is precipitated with digitonin, either before saponification (free cholesterol) or after saponification (total cholesterol), and the separated digitonide is purified and subjected to the Liebermann-Burchard color reaction. The color is then compared with that produced by a standard cholesterol solution.

**Procedure.<sup>107</sup>** Place approximately 10 ml. of the acetone-alcohol mixture in a 25-ml. glass-stoppered volumetric flask and add 1 ml. of serum or plasma down the side of the flask below the graduation. After withdrawing the pipet,

---

<sup>106</sup> Schoenheimer and Sperry: *J. Biol. Chem.*, **106**, 745 (1934); Sperry, *Am. J. Clin. Path.*, **8**, Tech. Suppl. 2, 91 (1938); Sperry (personal communication). See also Fitz: *J. Biol. Chem.*, **109**, 526 (1935); Sobel and Mayer: *J. Biol. Chem.*, **157**, 255 (1945). The original Schoenheimer-Sperry method is a microprocedure, requiring but 0.2 ml. of sample. The procedure described here is a slightly modified version which uses a larger sample, requires less technical skill, and has been found satisfactory for routine use in several laboratories.

<sup>107</sup> Reagents Required: *Acetone-Alcohol Mixture*. Mix 1 volume of absolute ethyl alcohol with 1 volume of redistilled acetone.

*Digitonin Solution*. Dissolve 400 mg. of digitonin (Hoffman-LaRoche, Nutley, N. J., or S. B. Penick and Co., 50 Church St., New York, N. Y.) in 100 ml. of distilled water. Filter or centrifuge just before use if not clear.

*10 Per Cent Acetic Acid Solution*. Dilute 1 volume of glacial acetic acid to 10 volumes with water, and mix.

*Acetone-Ether Mixture*. To 1 volume of redistilled acetone add 2 volumes of peroxide-free ether and mix. To prepare peroxide-free ether, wash ordinary ether with sodium sulfite, followed by water, and distill from calcium chloride.

*Potassium Hydroxide Solution*. Dissolve 10 g. of reagent-grade potassium hydroxide in 20 ml. of water. Store in a bottle equipped with a medicine dropper carrying a rubber bulb.

*Phenolphthalein Solution*. Dissolve 1 g. of phenolphthalein in 95 per cent alcohol and dilute to 100 ml.

*Acetic Acid*. Only the highest purity anhydrous product ("glacial") may be used.

*Acetic Anhydride-Sulfuric Acid Reagent*. Just before needed, place 20 ml. of acetic anhy-

swirl the flask to produce a finely divided precipitate, then immerse the flask in boiling water, with swirling to prevent bumping, until the solvent boils. Remove, cool to room temperature, and make up to volume with the alcohol-acetone mixture. Stopper, mix thoroughly, and pour onto a dry filter, collecting the clear filtrate in a dry test tube. Cover the funnel with a watch glass during filtration, to minimize evaporation of solvent.

*Precipitation of Free Cholesterol.* Transfer 6 ml. of filtrate to a 15-ml. centrifuge tube, add 3 ml. of digitonin solution, and 1 drop of 10 per cent acetic acid solution. Place a stirring rod in the tube and stir thoroughly. Place the tube, together with the stirring rod, in a pint or quart size preserving jar, cover the jar tightly, and allow to stand at room temperature overnight. In the morning, transfer the tube and rod to a test tube rack and stir gently to free particles of precipitate which may have adhered to the walls of the tube. Remove the rod carefully without touching the upper part of the tube and place it aside carefully so that no adherent precipitate is rubbed off; a wire rack with numbered positions is suggested, so that the rod may be returned to the proper tube later. Centrifuge the tube for about 15 minutes at about 2800 r.p.m. Decant the supernatant and drain in an inverted position for a few minutes, removing the last drop by touching the lip of the tube to a clean towel; or remove the supernatant by gentle suction through a fine capillary pipet, without stirring up the precipitate or touching the sides of the tube. A few particles may float at or near the top of the solution after centrifugation; they are discarded with the supernatant.

Replace the stirring rod in the tube and wash down the walls of the tube and the rod with 1.5 to 2 ml. of acetone-ether mixture added from a dropping pipet with attached rubber bulb. Stir the precipitate up thoroughly, replace the rod on the rack, and centrifuge the tube for 5 minutes. Remove the supernatant as above, and repeat the washing twice more, using ether instead of acetone-ether. Replace the rod in the tube and set aside until ready for color development.

*Saponification and Precipitation of Total Cholesterol.* Add 3 drops of potassium hydroxide solution to a 15-ml. graduated centrifuge tube, and add 3 ml. of the acetone-alcohol filtrate. Insert a stirring rod and stir vigorously until no droplets of alkali can be seen in the solution. Leave the rod in the tube, and place tube and rod in a preserving jar containing a layer of sand about 3 cm. deep which has been previously heated in a water bath until the temperature of the sand is about 45° C. The sand acts as a heat reservoir. Close the jar tightly and place in an incubator (37° to 40° C.) for 30 minutes. Remove the tube to a rack, allow it to cool to room temperature, raise the rod, and add alcohol-acetone mixture to the 6-ml. mark. Add 1 drop of phenolphthalein solution, followed by 10 per cent acetic acid, drop by drop

dride (Eastman) in a glass-stoppered cylinder and chill in ice water. When cold, add 1 ml. of concentrated sulfuric acid, a little at a time, with mixing and cooling during the addition. Stopper the cylinder, shake the contents vigorously for a few moments and return to the ice bath. Keep cold during use, and do not use any reagent more than 1 hour old. More or less of the reagent may be prepared as needed, using the same proportions.

*Stock Cholesterol Standard.* Dissolve 100 mg. of pure dry cholesterol in about 50 ml. of glacial acetic acid by warming on an electric hot plate and stirring. Transfer with rinsings to a 100-ml. glass stoppered volumetric flask, dilute to 100 ml. with acetic acid, and mix. This solution contains 1 mg. of cholesterol per ml. and is quite stable in the cold. It must be warmed to room temperature before using. *Dilute standard.* Transfer 5 ml. of stock standard, containing 5 mg. of cholesterol, to a 50-ml. glass-stoppered volumetric flask, dilute to the mark with acetic acid, and mix well. This solution contains 0.2 mg. of cholesterol in 2 ml.

with stirring, until the red color disappears. Add 1 drop in excess, followed by 3 ml. of digitonin solution. Stir thoroughly, place the tube and rod in a preserving jar, cover tightly, and allow to stand at room temperature for at least 3 hours, and preferably overnight. Separate and wash the precipitate exactly as described above for the precipitation of free cholesterol, except that only one ether washing instead of two is necessary.

**Development and Reading of Color.** Place a layer of sand about 3 cm. deep in a shallow pan and heat to 110° to 115° C. in an oven. Place the tubes containing the precipitated and washed cholesterol digitonide in the pan and return the pan to the oven.<sup>108</sup> After 30 minutes, remove the pan and, while the tubes are still in the hot sand, from a buret add 2 ml. of acetic acid in such a way that the acid washes down the wall of the tube and the rod. Stir well with the rod, allow to remain in the sand for about 2 minutes (not longer), remove and cool to room temperature, with the rod still in the tube. Undissolved material at this stage is neglected.

When the tubes are ready for color development, place them in a water bath at 25° C. from which light is excluded<sup>109</sup> and allow to come to temperature equilibrium. Note the time, and add 4 ml. of the cold acetic anhydride-sulfuric acid reagent, mix well with the rod, and return to the bath. Allow to stand 27 minutes, then transfer to colorimeter or photometer containers and read within the next 10 minutes. If possible, it is better to have the time of standing before reading constant at about 30–31 minutes.

A standard suitable for both colorimetric and photometric measurement is prepared as follows: Transfer 2 ml. of a standard solution of cholesterol in acetic acid, containing 0.2 mg. of cholesterol, to a suitable tube containing a stirring rod. Place in the water bath at 25° C. and allow to come to temperature equilibrium. When ready, add 4 ml. of the acetic anhydride-sulfuric acid reagent, mix, return to the bath, and allow to stand 27 minutes. Use within the next 10 minutes.<sup>110</sup> For photometric measurement, a blank is prepared similarly, except that 2 ml. of acetic acid alone is used instead of the standard cholesterol solution.

For colorimetric measurement, the colorimeter must be equipped with microcups and the eyepiece of the colorimeter must be provided with a red filter (Wratten No. 71A, supplied by Eastman Kodak Co. or by the manufacturer of the colorimeter). Arrange the time of color development so that the standard is ready first, and the unknowns reach the 27-minute stage at short intervals thereafter, depending upon the rapidity with which the color comparisons can be made. Adjust the standard against itself at 20 mm., and as each unknown becomes ready, rinse cup and plunger with a small portion and read against the standard. Do not use the standard after 37 minutes have elapsed from the start of color development; if more unknowns are present than can be read in this time, have a second standard suitably timed and ready for use.<sup>111</sup>

<sup>108</sup> This heating is to ensure complete removal of water from the hygroscopic digitonide precipitate.

<sup>109</sup> A large pan of water containing metal racks and placed in an enclosed box fitted with a door, or in a closet, is satisfactory. Insert a thermometer in the water and keep at 25° C. by adding hot or cold water as required.

<sup>110</sup> Because the standard appears to fade rapidly while it is in the colorimeter cup, Fitz (*loc. cit.*) suggests the preparation of a larger volume of standard, fresh portions of which are used at intervals during the 27 to 37 minute period of color development.

<sup>111</sup> Because of the instability of the standard, it has been suggested that when a number of analyses are being run colorimetrically, an artificial standard be used which is standardized each day against a cholesterol standard. Shapiro, Lerner, and Posen (*Proc. Soc. Exptl. Biol. Med.*, 32, 1300 (1935)) proposed a permanent artificial standard made from Carter's

For photometric measurement, transfer the colored solutions to suitable containers and determine the density in the photometer, at 625  $m\mu$ . Adjust the photometer to zero density against water, and determine the densities of the blank, the standard, and the unknowns at 30 to 31 minutes after adding the acetic anhydride-sulfuric acid reagent. Subtract the density of the blank from those of the standard and unknowns, to obtain the true densities.

**CALCULATION.** *For colorimetric measurement:* Since the amounts of filtrate taken for the free and total cholesterol determinations represent 0.24 and 0.12 ml. of original sample respectively, the calculations are as follows:

*Free Cholesterol.*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.2 \times \frac{100}{0.24} = \text{mg. free cholesterol per 100 ml.}$$

*Total Cholesterol.*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.2 \times \frac{100}{0.12} = \text{mg. total cholesterol per 100 ml.}$$

*For photometric measurement:*

*Free Cholesterol.*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.2 \times \frac{100}{0.24} = \text{mg. free cholesterol per 100 ml.}$$

*Total Cholesterol.*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.2 \times \frac{100}{0.12} = \text{mg. total cholesterol per 100 ml.}$$

At 625  $m\mu$ , and in a 1-cm. cuvette, the density of the standard is approximately 0.100<sup>112</sup> (Fig. 153). Under the conditions described, from 40 to 200 mg. per cent free cholesterol and 80 to 400 mg. per cent total cholesterol may be accurately determined.

FIG. 153. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED BY SCHOENHEIMER-SPERRY METHOD FOR CHOLESTEROL.

For standards containing (a) 0.2 mg., and (b) 0.4 mg. cholesterol. Solution depth, 1 cm.

Midnight Black Ink. Sperry and Brand (*J. Biol. Chem.*, 150, 351 (1943)) describe in detail the use of dilute naphthol green B solution as an artificial standard.

<sup>112</sup> Color developed for 30 to 33 minutes at 21° C.

For higher levels, repeat the analysis using less sample in the alcohol-acetone precipitation; or use less filtrate in the digitonin precipitation, with other reagents in proportion except for the final solution in acetic acid and color development; and correct the calculations accordingly.

Because of the sensitivity of the cholesterol color to bleaching by light, photometric measurements should be made as rapidly as possible, to avoid prolonged exposure to the light beam in the photometer.

**Interpretation.** Normal blood cholesterol appears to be maintained at a constitutional level which is characteristic for each individual, and from which large deviations do not ordinarily occur for that particular individual. Considerable variation, however, is found among different individuals, the normal range being from about 110 to 390 mg. per 100 ml. of serum or plasma. Of this, about one-third is present as free cholesterol (on the basis of digitonin precipitation, which is generally accepted as standard) and the remainder is esterified. Although many of the data in the literature are in terms of total cholesterol, the distribution of cholesterol between the free and the ester forms is attracting more attention, particularly in the diagnosis of liver disease. According to Sperry, routine determination of *whole blood* cholesterol should be abandoned, since the cells contain only free cholesterol and in quite constant amount, no changes in pathological conditions having been noted. Serum cholesterol is increased, and the determination has clinical value, in nephrosis, lipemia, diabetes mellitus, hypothyroidism, and biliary obstruction due to calculi or other causes. Increases are also found in pregnancy and after a high lipide diet. Decreased serum cholesterol is found in hyperthyroidism, pernicious anemia, and certain types of liver disease. In the latter condition, the proportion of ester cholesterol to total cholesterol may be sufficiently lowered to be of diagnostic significance. A low-cholesterol diet leads to lowered serum cholesterol; since there is ample evidence that cholesterol is synthesized within the body, changes in blood level due to diet presumably represent merely the net result of the various factors concerned.

## 2. Reinhold and Shiels' Modification of the Myers-Wardell Method:<sup>113</sup>

**Principle.** The serum or plasma is dried on anhydrous sodium sulfate and extracted with chloroform. The total cholesterol of the extract is determined colorimetrically by the Liebermann-Burchard reaction with acetic anhydride and sulfuric acid. In the original method of Myers and Wardell, plaster of Paris was used instead of sodium sulfate. Leiboff<sup>114</sup> describes a procedure in which the sample is dried on a small piece of absorbent paper which is then extracted in a specially designed flask. In the Bloor, Pelkan, and Allen<sup>115</sup> procedure, no special apparatus is necessary; proteins are precipitated with alcohol-ether mixture, an aliquot of the filtrate is dried in a beaker and extracted with successive small portions of hot chloroform. In all of these procedures, low results will be obtained if the extraction is incomplete.

<sup>113</sup> Myers and Wardell: *J. Biol. Chem.*, **36**, 147 (1918); Reinhold and Shiels: *Am. J. Clin. Path.*, **6**, 22 (1936).

<sup>114</sup> Leiboff: *J. Biol. Chem.*, **61**, 177 (1924); *J. Lab. Clin. Med.*, **10**, 857 (1925); **11**, 777 (1926); **15**, 776 (1930).

<sup>115</sup> Bloor, Pelkan, and Allen: *J. Biol. Chem.*, **52**, 191 (1922). See also Kelsey: *J. Biol. Chem.*, **127**, 15 (1939).

**Procedure.**<sup>116</sup> Transfer 1 ml. of plasma or serum to a small mortar containing about 8 g. of anhydrous sodium sulfate. Mix uniformly, dry in an oven at 100° C. for 10 minutes, cool in a desiccator, pulverize, and transfer completely to a paper extraction shell which is then inserted into a Soxhlet extraction tube (see Fig. 154) suspended from the condensing coil of the extraction apparatus. (If the extraction apparatus illustrated in Fig. 154 is not available, Myers' arrangement shown in Fig. 155 may be used, in which the extraction tube is a perforated glass tube (2.5 × 7 cm.) and is connected to

FIGS. 154 AND 155. EXTRACTION APPARATUS FOR CHOLESTEROL DETERMINATION.

Fig. 155 after Myers: *Practical Chemical Analysis of Blood*, 2d ed., C. V. Mosby Co., St. Louis.

a reflux condenser as illustrated.) Place 20 to 25 ml. of redistilled chloroform in the extraction flask, place on an electric hot plate, and extract for 90 minutes, during which time cold water flows through the condenser or coil. Allow the extract to cool and transfer with rinsings to a 25-ml. volumetric flask. Make up to volume with chloroform, mix well, and filter through a dry filter if necessary.

Transfer 10 ml. of the chloroform extract to a dry test tube and add 2 ml. of the freshly prepared acetic anhydride-sulfuric acid reagent. Treat 10 ml. of a standard solution of cholesterol in chloroform, containing 0.8 mg. of

<sup>116</sup> Reagents Required: *Anhydrous sodium sulfate*, reagent grade.

*Chloroform.* Commercial chloroform should be washed with water, dried over anhydrous potassium carbonate, and distilled. Dry the distillate over phosphorus pentoxide and again distil. Keep protected from light. Present-day reagent-grade chloroform (such as Merck's) may be satisfactory without the necessity of further treatment.

*Acetic Anhydride-Sulfuric Acid Reagent.* Just before use, add 1 volume of concentrated sulfuric acid slowly with shaking to 10 volumes of acetic anhydride. Prepare only enough reagent for a particular series of analyses, and discard the unused portion.

*Cholesterol Standard. Stock Standard.* Dissolve 160 mg. of pure dry cholesterol in chloroform and transfer with washings of chloroform to a 100-ml. flask. Make up to volume with chloroform and mix. This solution contains 8 mg. of cholesterol in 5 ml. Keep cold and away from light. To prepare the dilute working standard, transfer 5 ml. of stock standard to a 100-ml. volumetric flask, dilute to the mark with chloroform, and mix. This solution contains 0.8 mg. of cholesterol in 10 ml. It is stable for some days if kept cold and away from light.

cholesterol, in the same way, and for photometric measurement prepare a blank by treating similarly a 10-ml. portion of chloroform alone. After mixing, keep in a dark place at 25° C. for exactly 30 minutes,<sup>109</sup> then transfer to colorimeter or photometer containers and read.

For colorimetric measurement, compare the unknown against the standard in the usual way. The colorimeter may be equipped with a light filter over the eyepiece (Wratten No. 71A or its equivalent, supplied by Eastman Kodak Co. or by the manufacturer of the colorimeter) although this is not essential. Since the standard color fades rapidly, if more than two or three unknowns are to be read, a number of standards must be prepared, suitably timed with respect to the unknowns, or the standard may be used to standardize an artificial standard (see previous method) against which the properly timed unknowns are read.

For photometric measurement, determine the densities of the blank, standard, and unknown at exactly 30 minutes after adding the acetic anhydride-sulfuric acid reagent, in a photometer at 660 m $\mu$ . Set the photometer to zero density with water. Subtract the density of the blank from the other values to obtain their true densities.

CALCULATION. *For colorimetric measurement:* Since the 10 ml. of extract used correspond to 0.4 ml. of original sample, the calculation is as follows:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.8 \times \frac{100}{0.4} = \text{mg. cholesterol per 100 ml.}$$

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.8 \times \frac{100}{0.4} = \text{mg. cholesterol in 100 ml.}$$

Under the conditions specified, and in a 1-cm. cuvette, the density of the standard is approximately 0.700. Since the standard corresponds to a serum with 200 mg. per cent cholesterol, the limit of accurate measurement under these conditions is about 300 mg. per cent. It is suggested for photometric measurement that smaller aliquots, such as 2 ml. or 5 ml., of the chloroform extract be taken, diluted to 10 ml. with chloroform, and the color then developed as described. Using the above calculation formula, results must then be multiplied by 5 or 2 respectively. In this way a much wider range of cholesterol concentration may be accurately covered.

**Discussion.** The final color in the above procedure is due to both free cholesterol and cholesterol esters. Since free cholesterol and ester cholesterol give different amounts of color per milligram, and the color develops at different rates, interpretation of results may be obscure if an abnormal distribution of cholesterol between free and ester forms is present. Reinhold<sup>117</sup> utilizes the difference in velocity of the Liebermann-Burchard reaction with cholesterol esters and free cholesterol as a basis for determination of cholesterol partition. Sperry and Brand<sup>118</sup> describe a procedure for total cholesterol after saponification of the ester fraction, thus eliminating errors due to variation in ester content.

The Liebermann-Burchard reaction with cholesterol gives much more color in chloroform than in the glacial acetic acid used in the previous method. To offset this advantage, the reaction in chloroform is, according to Schoenheimer and Sperry, more sensitive to the effect of such analytical variables as time, temperature, etc., so that more careful technical

<sup>117</sup> Reinhold: *Proc. Soc. Exptl. Biol. Med.*, **32**, 614 (1935).

<sup>118</sup> Sperry and Brand: *J. Biol. Chem.*, **150**, 351 (1943).

control is necessary. The spectrophotometric characteristics of the color in chloroform are somewhat similar to those of the color in acetic acid (see Fig. 153) except that peak light absorption in the red end of the spectrum is at  $660\text{ m}\mu$  instead of at  $625\text{ m}\mu$ .<sup>119</sup> The high light absorption at  $420\text{ m}\mu$  permits use of this range as well as the  $660\text{ m}\mu$  range. Although the color intensity here slowly increases rather than waxing and waning as at  $625\text{ m}\mu$ , and is a function of the extent of exposure to light during color development, nevertheless Summerson and Robinson<sup>120</sup> found this range to be in some respects more satisfactory than at  $660\text{ m}\mu$ . Sunderman and Razek<sup>119</sup> have shown that measurement at  $530\text{ m}\mu$  is also satisfactory; although the optical density is low here, the agreement with Beer's law is excellent.

**Interpretation.** See under previous method.

**Other Methods.** Other methods for the determination of serum cholesterol usually employ isolation as the digitonide, followed either by weighing on a microbalance,<sup>121</sup> or oxidation with chromic acid. In the oxidation procedures, either titrimetric<sup>122</sup> or gasometric<sup>123</sup> methods may be employed. For details, see the original papers.

## DETERMINATION OF FATTY ACIDS

**Introduction.** The fatty acids of blood are present largely as esters in the form of (a) neutral fat, (b) phospholipides, (c) cholesterol esters; there may be a small amount of free fatty acid (i.e., soaps) also present. The total fatty acids of whole blood are distributed approximately evenly between cells and plasma; this even distribution apparently simply reflects the fact that while phospholipides for example are much more abundant in the cells than in the plasma, the reverse is true for esterified cholesterol, which is apparently absent from the cells. Total fatty acid content is usually determined by saponification and titration of the liberated fatty acids.

**Method of Stoddard and Drury:**<sup>124</sup> **Principle.** The blood is extracted with alcohol-ether, the extract saponified, the fatty acids separated, filtered, washed, dissolved in alcohol, and titrated with thymol blue as indicator.

**Procedure:** **EXTRACTION.** Five ml. of whole blood, plasma, or serum is introduced gradually into a 100-ml. volumetric flask containing about 75 ml. of a mixture of 95 per cent alcohol and redistilled ether (3:1). The flask is immersed in boiling water and rotated frequently and vigorously (to prevent superheating) until boiling begins, then cooled to room temperature, made up to volume with alcohol-ether, mixed, and filtered through fat-free filter paper.

**Saponification.** To a 100-ml. beaker containing a few grains of coarse sand (previously boiled with acid, washed, dried, and extracted with ether) add

<sup>119</sup> Sunderman and Razek: *J. Biol. Chem.*, **118**, 379 (1937).

<sup>120</sup> Unpublished.

<sup>122</sup> Okey: *Proc. Soc. Exptl. Biol. Med.*, **26**, 518 (1929); Turner: *J. Biol. Chem.*, **92**, 495 (1931).

<sup>123</sup> Kirk, Page, and Van Slyke: *J. Biol. Chem.*, **106**, 203 (1934).

<sup>124</sup> Stoddard and Drury: *J. Biol. Chem.*, **84**, 741 (1929). This method has been critically evaluated by Man and Gildea: *J. Biol. Chem.*, **99**, 43 (1933).

gradually, while evaporating on a water bath, 75 ml. of the filtrate. The temperature should be low enough to avoid perceptible boiling but may be raised after the ether has evaporated. Evaporate to a volume of about 30 ml. Add 0.1 ml. of saturated  $\text{CO}_2$ -free  $\text{NaOH}$ ,<sup>125</sup> mix, add a few grains more of sand, cover with a watch glass, and boil gently for 20 to 30 minutes (to saponify).

*Separation and Washing.* Remove the watch glass, drop in a small piece of litmus paper, make acid with 30 per cent  $\text{HCl}$ ; then run back to alkalinity with 10 per cent  $\text{NaOH}$  (in order to avoid an excess of alkali on evaporating to dryness). Evaporate to dryness (in order to get rid of all alcohol). Add 15 ml. of water, heat on the steam bath, and stir to dissolve the soaps. While hot, add a drop of thymol blue indicator and make acid (faint pink) with 30 per cent  $\text{HCl}$ . Set the beaker for 10 minutes in cold water, then swirl almost continuously for five minutes to produce a better separation of the fatty acids.

Filters are previously prepared as follows: Use a Gooch crucible, smallest size (top 28 mm., bottom 18 mm. in diameter). Set the crucible in a rubber holder which fits over a 500-ml. suction flask. A paper-pulp suspension is made by shaking up a piece of soft filter paper in 300 to 400 ml. of distilled water. Shake vigorously and immediately pour some into the crucible while there is a strong suction on. Repeat until a layer about 1 mm. thick is formed. Tamp the layer down carefully all over with the end of a glass rod. Allow the larger masses of filter pulp fibers in the suspension to settle out, and pour on successive amounts of the thin upper suspension of isolated shreds, keeping a strong suction on and tamping down occasionally, until the filter is dense enough to offer a definite resistance to the suction. Remove the crucible from the rubber holder and dry in an air oven at  $110^\circ \text{C}$ . for 15 minutes. Allow to cool before using.

Place the crucible in its holder in an ordinary funnel and filter some of the fatty acid suspension into a test tube. If the filtrate is not perfectly clear, put it through the crucible again. If the filtration does not start in a few minutes, transfer the crucible and rubber holder to the filter flask and start the suction very gently, with a test tube under the funnel. After filtration has started, continue without suction. After the fatty acid suspension is filtered and drained, wash with 4 ml. of 5 per cent  $\text{NaCl}$  solution, neutralized to methyl red. Use a pipet and run the salt solution down the walls of the beaker all around; then, tipping the beaker, use a fine bent glass rod to rinse the side of the beaker more thoroughly with the solution; then pour this rinsing into the Gooch crucible, rinsing its side with the aid of the rod. Wash until the filtrate from one washing takes not more than 0.05 ml. of 0.02 N  $\text{NaOH}$  to neutralize it to phenolphthalein. Usually this is true of the third washing. Put the crucible back on the suction flask with a nonprotein nitrogen tube (cut off to a convenient height and calibrated at 1-ml. intervals from 10 to 15 ml.) under the funnel. Wash down the walls of the beaker with 5 ml. of 95 per cent alcohol, heat to boiling, and pour into the crucible. With the glass rod quickly loosen up any fatty acid fragments on the wall of the crucible. Allow to run nearly out, then put on a moderate suction. Rinse out the beaker and crucible twice more with 3 ml. of alcohol each time, heating it to boiling. Then wash off the outside of the crucible and the funnel.

*Titration.* Add a few grains of sand, boil the filtrate for 1 minute, cool in a beaker of water, note the volume of alcohol, add 3 drops of 0.3 per cent thymol blue in 50 per cent alcohol, titrate with 0.02 N  $\text{NaOH}$  to a pure blue which stays practically unchanged (no yellow tinge) while shaking for 2

<sup>125</sup> See Appendix.

minutes, keeping a stopper in the mouth of the tube to avoid absorption of CO<sub>2</sub>. For a blank boil 10 ml. of alcohol and titrate.

**CALCULATION.** Calculate the correction necessary for the amount of alcohol present before titration. Add a correction amounting to 0.005 ml. for each ml. of NaOH used in titration (a simple correction for the volume of solution). Subtract the total correction from the titration. Multiply by the normality factor, thus getting the number of millimoles of fatty acid. Multiply by

$$\frac{100}{\text{ml. filtrate evaporated}} \times \frac{100}{\text{ml. blood used}} = \text{millimoles fatty acid per 100 ml. blood}$$

To translate into terms of weight (not a very significant figure), multiply by an average factor for the fatty acids as they usually occur in blood = 277.2. The molecular weights are so nearly alike that a considerable variation in the proportions will not affect the calculated weight by more than about 2 per cent.

**Interpretation.** Human whole blood has a total fatty acid content ranging from about 9 to 14 millimoles (milliequivalents) per liter. This corresponds to about 250 to 390 mg. of average fatty acids per 100 ml. Some variation is found between different individuals, and in a particular individual at various times. Factors such as diet and disease which influence the blood content of neutral fat, phospholipide, and cholesterol esters will naturally influence the total fatty acid content.

## DETERMINATION OF LIPIDE PHOSPHORUS

**Introduction.** The lipide phosphorus of blood and tissues is found in such compounds as lecithin, cephalin, sphingomyelin, phosphatidyl serine, etc., which are obtained by the extraction of tissues with certain nonaqueous solvents. In blood plasma, lecithin is the major phospholipide according to Bloor, while in the red cells cephalin and sphingomyelin predominate; the data of Kirk<sup>126</sup> present a somewhat different picture. The simplest procedure for the determination of phospholipide is the analysis of lipide-containing extracts for total phosphorus, as described below; this procedure gives fairly accurate results. Bloor<sup>127</sup> isolates phospholipides from nonlipide phosphorus by precipitation with acetone and magnesium chloride, and determines the phospholipide titrimetrically after oxidation with chromic acid. Gasometric determination as total carbon by wet combustion is also satisfactory.<sup>128</sup> Kirk<sup>126</sup> and Artom<sup>126</sup> have described procedures for the separate microdetermination of certain of the various phospholipides in blood.

**Method of Youngburg,<sup>129</sup> Modified: Principle.** The extracted lipides are oxidized with sulfuric acid and hydrogen peroxide and the phosphate present determined colorimetrically. The phosphate procedure of Fiske and Subbarow is applied here; the Youngburgs use the stannous chloride reagent of Kuttner and Cohen (see p. 630) which is applicable to smaller amounts of phosphorus.

<sup>126</sup> Kirk: *J. Biol. Chem.*, **123**, 623, 637 (1938). See, however, Sinclair and Dolan: *J. Biol. Chem.*, **142**, 659 (1942); Artom: *ibid.*, **157**, 595 (1945).

<sup>127</sup> Bloor: *J. Biol. Chem.*, **82**, 273 (1929). For an adaptation of this method, see Ellis and Maynard: *J. Biol. Chem.*, **118**, 701 (1937). McCoy and Schultze (*J. Biol. Chem.*, **156**, 479 (1944)) describe a photometric adaptation of the chromic acid oxidation procedure, suitable for small amounts of lipides.

<sup>128</sup> Kirk, Page, and Van Slyke: *J. Biol. Chem.*, **106**, 203 (1934); Van Slyke and Folch: *ibid.*, **136**, 509 (1940).

<sup>129</sup> Youngburg and Youngburg: *J. Lab. Clin. Med.*, **16**, 158 (1930).

**Procedure.** Transfer 18 ml. of alcohol-ether mixture<sup>130</sup> to a wide-mouthed test tube (best 150 by 20 mm.) graduated at 20 ml., and drop in slowly, while shaking, 1 ml. of plasma or serum. Mix, place in a boiling water bath, and heat the contents of the tube to boiling. Remove and allow to cool to room temperature. Make up to the 20-ml. mark with alcohol-ether mixture, mix, and filter.

Transfer 8 ml. of filtrate to a 200 by 25 mm. pyrex test tube, add a silica pebble (from broken silica ware), place in a wire rack containing a wire bottom, over an electric hot plate, and evaporate to dryness.

Add 2.5 ml. of 5 N sulfuric acid to the residue in the tube and digest over the hot plate as in the method for total acid-soluble phosphorus (see p. 633), including oxidation with perhydrol (30 per cent hydrogen peroxide). The remaining procedure is the same as for total acid-soluble phosphorus of blood (see p. 633), with color development at a final volume of 25 ml.; a different standard is however used, containing only half as much inorganic phosphate, i.e., 0.5 ml. of standard phosphate solution, containing 0.04 mg. of inorganic phosphate, instead of the 1 ml. specified on p. 634. The conditions for colorimetric or photometric measurement of the color intensity are the same as for acid-soluble phosphorus.

**CALCULATION.** Since the 8 ml. of extract represent 0.4 ml. of original sample, calculation of results is similar to that for acid-soluble phosphorus except that the value 0.04 replaces 0.08 in the calculations, corresponding to the use of half as strong a standard. Or calculate as for acid-soluble phosphorus and divide the result by 2, to obtain mg. of lipide phosphorus per 100 ml. of original sample.

**Interpretation.** Plasma or serum contains about 9 to 10 mg. of lipide phosphorus per 100 ml.; whole blood slightly more, averaging about 12 mg. per cent. These values may be expressed as lecithin by multiplying by 25, since lecithin contains approximately 4 per cent phosphorus; it is known, however, that only part of the total blood phospholipides is represented by lecithin. Artom (*loc. cit.*) gives the following distribution of phospholipides for a sample of human plasma: lecithin, 55 per cent of the total phospholipides; phosphatidyl ethanolamine (cephalin), 21 per cent; sphingomyelins, 12 per cent; phosphatidyl serine, 7 per cent. Little is known concerning the pathological significance of variation in this distribution. Pathological variation in total phospholipide content is greater for red cells than for plasma. In diabetes and nephritis, the lipide phosphorus follows roughly the degree of lipemia. Increases in lecithin are also noted in pregnancy and in certain hepatic conditions. The existence of a constant ratio between cholesterol (which is antihemolytic) and lecithin (hemolytic) has not been definitely established.

## DETERMINATION OF BILE PIGMENT IN SERUM

**1. Icteric Index (Meulengracht): Principle.** The intensity of yellow pigmentation of serum is compared with a standard potassium bichromate solution.

**Procedure.**<sup>131</sup> Separate the serum from 4 or 5 ml. of freshly drawn unhemolyzed blood. For colorimetric measurement, accurately dilute 1 ml. of serum

<sup>130</sup> *Alcohol-Ether Mixture:* Three volumes of 95 per cent redistilled alcohol and 1 volume of redistilled ether. Mix.

<sup>131</sup> *Reagents Required: 5 Per Cent Sodium Citrate Solution.* Dissolve 50 g. of U.S.P. or C.P. sodium citrate in water and dilute to 1 liter. If turbid, allow to stand several days and

with 5 per cent sodium citrate solution in a small graduated cylinder, according to its color, until an approximate match with the standard potassium bichromate solution is obtained. Transfer to a colorimeter cup and compare against the standard bichromate.

For photometric measurement, dilute 1 ml. of serum to 10 ml. with 5 per cent sodium citrate solution. Determine the density in a photometer at 420  $m\mu$ , setting the photometer to zero density with the 5 per cent sodium citrate solution alone. Determine the density of the standard potassium bichromate solution at the same wavelength, using water as a blank.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{Dilution} = \text{Icteric Index}$$

For example, if 1 ml. of serum is diluted to 6 ml., the dilution is 6, and if the unknown exactly matches the standard in the colorimeter, the icteric index is 6.0.

*For photometric measurement:* Since the standard bichromate solution has an equivalent icteric index of 10 under the conditions of the procedure, the calculation is as follows:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 10 = \text{Icteric Index}$$

In a 1-cm. cuvette at 420  $m\mu$ , an icteric index of 10 gives a density reading of approximately 0.200, at a 1:10 dilution of the serum. Under these conditions, the limit of accurate measurement corresponds to an icteric index of approximately 50. For higher values, the determination is repeated at a greater dilution of the serum, the new dilution value replacing the 10 in the above calculation formula. Since the standard is a stable colored solution, its density should be constant. Therefore, once the density of the standard has been established for a given photometer and wavelength or filter, this value may be used in the future without the necessity of repeating the reading of the standard in every series of analyses.

**Interpretation.** The normal icteric index ranges between 4 and 6. The zone of latent jaundice (i.e., hyperbilirubinemia without clinical signs of jaundice) is between 6 and 15. Above this value icteric symptoms may be observed. The yellow color is considered to be due chiefly to the presence of bilirubin, an icteric index of 5 corresponding roughly to 0.1 to 0.2 mg. of bilirubin per 100 ml. of serum. The presence of certain other pigments will lead to errors; hemolysis in particular is to be avoided. This may be done by using a dry syringe and needle for collecting the blood, allowing the blood to clot protected from light, and centrifuging sharply to obtain a clear serum. Blood should be drawn before breakfast to avoid chyle; lipemic sera cannot be used because of interfering turbidity. The carotinemia which follows ingestion of carrots will lead to a high apparent icteric index and false interpretation; carrots should not be eaten the day before the test. Further aspects of the significance of serum bilirubin are discussed below.

---

filter. Add a little chloroform as a preservative. Saline solution (0.9 per cent sodium chloride) may also be used as a diluent in the colorimetric procedure, but citrate gives clearer solutions.

*Standard Potassium Bichromate (0.01 Per Cent).* Dissolve exactly 0.1 g. of reagent-grade potassium bichromate in water, transfer with rinsings to a 1-liter volumetric flask, add 2 to 3 drops of concentrated sulfuric acid, dilute with water to the mark, and mix. Keep in a brown glass bottle. The icteric index of this solution is arbitrarily defined as equal to 1.

**2. Van den Bergh Test:**<sup>132</sup> **Principle.** Plasma or serum is treated with Ehrlich's reagent (diazotized sulfanilic acid). Bilirubin present reacts with the reagent to form a colored compound known as *azorubin* or *azobilirubin*.<sup>133</sup> Qualitatively, the color may develop immediately ("direct reaction") or on standing ("indirect reaction"). Occasionally an atypical color develops almost immediately ("biphasic reaction"). Quantitatively, the color may be used as a measure of the bilirubin content of the serum or plasma (see Section 3, p. 593).

**Procedure.**<sup>134</sup> Obtain unhemolyzed plasma or serum as described above. Jaundiced serum must be diluted 1:5 or, if highly colored, 1:10, with water. To 1 ml. of serum (generally diluted), add 2 ml. of freshly prepared Ehrlich's diazo reagent.<sup>135</sup> **Direct reaction:** a pink to purple color develops immediately, reaching maximum intensity in a minute or so. **Indirect reaction:** no color change is noted during the first 2 minutes. Within 10 minutes a golden color forms, changing over a period of an hour or more through brown to pink.<sup>136</sup> **Biphasic reaction:** a color appears during the first 2 minutes, but it is brownish-red rather than the typical pink or purple of the direct reaction.

**Interpretation.** The chemical and clinical significance of the three types of Van den Bergh reaction has been the object of considerable investigation. Van den Bergh believed that the different reactions were dependent upon the path by which the pigment entered the serum. For example, the direct reaction is usually found in the condition of obstructive jaundice, i.e., when the biliary passages are blocked, preventing the excretion of bile pigment which has already been secreted by the liver cells. The indirect reaction is usually found when the jaundice is of hemolytic or extrahepatic origin, and the biphasic reaction is thought to represent a combination of both types. Further study has not justified the belief that the various types of jaundice may be distinguished in terms of the qualitative Van den Bergh test.<sup>137</sup> While normal sera and sera from cases of hemolytic jaundice usually show no direct-reacting bilirubin, in most other types of jaundice it is usually possible to demonstrate the presence of both direct-reacting and indirect-reacting bilirubin. It appears probable that there are two distinct types of serum bilirubin; for

<sup>132</sup> Van den Bergh: *Presse méd.*, **29**, 441 (1921); Sepulveda and Osterberg: *J. Lab. Clin. Med.*, **28**, 1359 (1943). See also Ducci and Watson: *J. Lab. Clin. Med.*, **30**, 293 (1945).

<sup>133</sup> Pyrroles couple with diazotized sulfanilic acid if they have free  $\alpha$  or  $\beta$  positions or substituted groups that are readily displaced, such as carboxyl. (The  $\alpha$  carbon is that adjacent to the N in the ring). It is believed that bilirubin is split into two dipyrrolyl compounds, neoxanthobilirubic acid and isoneoxanthobilirubic acid, by the diazo reagent. Each of these has a free  $\alpha$  position which permits coupling to occur. The term azobilirubin is loosely used to describe the mixture of azo pigments produced.

<sup>134</sup> Reagents Required: **Diazo Reagent—Solution A.** To 1 g. of sulfanilic acid add 15 ml. of concentrated hydrochloric acid. Add water, stir to dissolve, and dilute to 1 liter with water. **Solution B.** Dissolve 0.5 g. of sodium nitrite in water and dilute to 100 ml. Just before the test, prepare the *diazo reagent* by mixing 25 ml. of Solution A with 0.75 ml. of Solution B. This mixed solution keeps only a short time at room temperature.

<sup>135</sup> Better results are sometimes obtained by adding the diazo reagent slowly down the side of the test tube containing the serum so that a layer is formed over the serum. Observe the color at the interface between serum and reagent.

<sup>136</sup> The indirect test is frequently carried out by adding three to four volumes of alcohol to the mixture of serum and reagent after 10 minutes. The indirect color appears immediately after mixing.

<sup>137</sup> See Greene, Plotz, and Localio: *Arch. Int. Med.*, **61**, 658 (1938); Sepulveda and Osterberg: *ibid.*, **72**, 372 (1943); also pp. 402–404 in Bodansky and Bodansky, "Biochemistry of Disease," 2nd ed, New York, The Macmillan Co., 1952.

instance, indirect-reacting bilirubin may be removed from serum by extraction with chloroform, while direct-reacting bilirubin is not soluble in this solvent. Griffiths<sup>138</sup> has reported the isolation from human bladder bile of a pigment called "cholebilirubin" which gives the direct reaction, is distinct chemically from bilirubin, and appears to have the properties of the direct-reacting bilirubin of serum. It has been proposed that the terms "cholebilirubin" and "hemobilirubin" be used for the direct-reacting and indirect-reacting bilirubin respectively; these terms carry the unfortunate implication of origin, which has not been conclusively established. Other interpretations of the Van den Bergh reaction which have been proposed include the theory that variations are due to concentration differences,<sup>139</sup> or that the bilirubin of plasma is bound to protein, with a portion capable of dissociating to give an immediate reaction ("direct-reacting") while the remainder ("indirect-reacting") can react only slowly or after the addition of alcohol.<sup>140</sup> No single theory has apparently found universal acceptance.<sup>141</sup>

**3. Quantitative Determination of Serum Bilirubin (Method of Malloy and Evelyn):**<sup>142</sup> **Principle.** The principle is the same as that used in the qualitative Van den Bergh reactions described above. The "azobilirubin" formed is determined by photometric measurement.

**Procedure.**<sup>143</sup> Dilute 1 ml. of unhemolyzed plasma or serum to 10 ml. with water, and mix. **Blank:** Place 5 ml. of absolute methyl alcohol in a test tube. Add 1 ml. of the blank hydrochloric acid solution, mix by tapping, and add 4 ml. of the 1:10 diluted serum or plasma. Mix gently by inversion. **Unknown:** Place 5 ml. of absolute methyl alcohol in a second test tube. Add 1 ml. of freshly prepared diazo reagent, mix by tapping, and add 4 ml. of the 1:10 diluted serum or plasma. Mix gently by inversion. Care must be taken to handle both blank and unknown tubes in the same manner, so that any turbidity which may form will be the same in both tubes. Allow to stand 30 minutes for color development, then transfer to suitable containers and read in the photometer at 540 m $\mu$ . Set the photometer to zero density with the blank. This compensates for any extraneous color or turbidity present in the unknown.

<sup>141</sup> For review see Gray: *The Bile Pigments*, New York, John Wiley & Sons, 1953.

<sup>142</sup> Malloy and Evelyn: *J. Biol. Chem.*, **119**, 481 (1937).

<sup>143</sup> Reagents Required: *Absolute Methyl Alcohol*.

**Diazo Reagent: Solution A.** To 1 g. of sulfanilic acid add 15 ml. of concentrated hydrochloric acid, dissolve and dilute with water to 1 liter. Stable indefinitely. **Solution B.** Dissolve 0.5 g. of sodium nitrite in water and dilute to 100 ml. Keep away from light, and discard when it turns yellow. **Diazo Reagent.** Mix 10 ml. of Solution A with 0.3 ml. of Solution B. Must be prepared fresh before using.

**Blank Hydrochloric Acid Solution.** Dilute 15 ml. of concentrated hydrochloric acid to 1 liter with water. Stable indefinitely.

**Standard Bilirubin Solution: Stock Standard.** Place 10 mg. of bilirubin (obtainable from Eastman Kodak Co., Rochester, N.Y., or Hoffmann-La Roche, Nutley, N.J.) in a 100-ml. volumetric flask, add chloroform to dissolve, and dilute to 100 ml. with chloroform. Keep in a dark bottle in the cold. **Dilute standard.** Transfer 10 ml. of stock standard to a 100-ml. volumetric flask and dilute to the mark with methyl alcohol. Mix. This standard contains 0.01 mg. of bilirubin per ml. Prepare just before using.

## CALCULATION.

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{mg. bilirubin in standard} \times \frac{10}{4} \times 100$$

$$= \text{mg. bilirubin per 100 ml. serum or plasma}$$

The density of the standard is established as follows: Transfer 4 ml. of dilute standard alcoholic solution of bilirubin, containing 0.04 mg. of bilirubin, to a test tube, and add 5 ml. of methyl alcohol, followed by 1 ml. of diazo reagent. Mix by inversion and allow to stand 30 minutes for color development. At the same time, prepare a blank tube containing 9 ml. of methyl alcohol and 1 ml. of diazo reagent. Mix. After 30 minutes, set the photometer to zero density at 540  $m\mu$  with the blank tube and determine the density of the standard.

Under the conditions specified, and in a 1-cm. cuvette, the standard has a density of approximately 0.300 (see Fig. 156). Since this standard corresponds in an analysis to a

FIG. 156. ABSORPTION SPECTRUM OF AZO-BILIRUBIN, AS OBTAINED IN MALLOY-EVELYN BILIRUBIN METHOD.

serum bilirubin content of 10 mg. per cent, up to about 30 mg. per cent of bilirubin may be accurately determined. If the value is above this, dilute the contents of both blank and unknown tubes with an equal volume of 50 per cent methyl alcohol, read immediately, and multiply the results by 2.

The color developed in this procedure is quite stable and reproducible. Since bilirubin is expensive and the standards do not keep very well, it is feasible to determine the standard density once carefully for a given photometer and wavelength setting or filter, and to use this value in future analyses, without the necessity of repeating the reading of the standard each time.

If a photometer is not available, the unknown may be compared in a colorimeter against the standard in the usual manner. A green filter over the eyepiece of the colorimeter will aid in color matching. An artificial standard containing cobalt sulfate has been suggested for visual colorimetry,<sup>144</sup> to replace the bilirubin standard. A colorimetric method has been described by Gibson and Goodrich.<sup>145</sup>

**Interpretation.** Normal plasma or serum contains 0.1 to 0.25 mg. of bilirubin per 100 ml. Bilirubin content is sometimes expressed in "units," 1 unit corresponding to 0.5 mg. per cent; thus normal plasma contains 0.2 to 0.5 unit. The zone of latent jaundice is represented by the range of 0.25 to 1.0 mg. per cent. Hyperbilirubinemia may occur in diseases of the liver or biliary tract, and also in extrahepatic conditions of a hemolytic

<sup>144</sup> White: *Brit. J. Exptl. Path.*, **13**, 76 (1932).

<sup>145</sup> Gibson and Goodrich: *Proc. Soc. Exptl. Biol. Med.*, **31**, 413 (1934).

nature, such as those accompanying infectious diseases, pernicious anemia, hemolytic anemia, hemorrhage, etc. Low values for bilirubin may be found in secondary anemia. The determination may therefore be of importance in the differential diagnosis of anemias. The renal threshold for bilirubin is 3.5 to 4.0 units (1.7 to 2.0 mg. per cent) in the plasma.

## THYMOL TURBIDITY AND FLOCCULATION TEST

**Principle.** Maclagan<sup>146</sup> discovered that thymol, in barbital buffer at low ionic strength, added to serum produced marked turbidity in the presence of parenchymatous liver disease. In addition, flocculation often appeared on longer standing.

The thymol-barbital reagent is saturated with thymol. Temperature and other factors influencing solubility must be considered in preparing the solution. The procedure described<sup>147</sup> permits better control of thymol concentration and pH and yields a more uniform reagent of improved stability.

**Procedure.**<sup>148</sup> Measure 6 ml. of thymol-barbital reagent into a photometer cuvette. Place the tubes in a water bath maintained at 25° C.  $\pm$  1°. Add 0.1

<sup>146</sup> Maclagan: *Brit. J. Exp. Path.*, **25**, 234 (1944).

<sup>147</sup> Reinhold and associates. Personal communication.

<sup>148</sup> Reagents Required: *Thymol-Barbital Reagent*. Transfer 6.0 g. of thymol crystals (colorless) to a 2000-ml. pyrex Erlenmeyer flask. Heat 1000 ml. of distilled water to boiling in another flask and boil it for about five minutes to remove carbon dioxide. Allow the water to cool to about 95°, and pour about 300 ml. into the flask on the thymol, which will melt and partially dissolve. Add 3.09 g. barbital and 1.69 g. sodium barbital and the remainder of the hot water to the flask containing the thymol. Without delay, stopper the flask and mix by rotating vigorously for about five minutes. Allow the solution to cool gradually to room temperature. Transfer the reagent to a volumetric flask of 1000 ml. capacity and dilute to the mark with distilled water. Return the solution to the original flask. Add about 1 g. of thymol crystals. Shake vigorously until the solution becomes clear. Allow the flask to stand at 25  $\pm$  1° overnight preferably in a constant temperature bath. Mix again and filter through Whatman No. 1 paper, maintaining the temperature of the solution at or near 25° C. Test the pH which should be 7.55  $\pm$  0.03. The pH may be adjusted by adding 0.1 N NaOH if the reagent is too acid, or by shaking in the presence of a little CO<sub>2</sub> if too alkaline. Expired air may be used as a convenient source of CO<sub>2</sub>.

The optimal temperature at which to keep the reagent appears to be 15°, however at a room temperature of 25° C., the reagent remains unchanged for at least two weeks. At temperatures lower than 15° it is more stable but crystals may separate thus causing lower values for thymol turbidity. Remove sufficient solution for one day's use and place it in a bath at 25° C. at least 30 minutes before using. Exposure to carbon dioxide should be kept to a minimum. The reagent should be renewed when it becomes opalescent.

**Standards.** Turbidity can be measured either visually or photometrically. The latter is recommended. For photometric measurement, colloidal glass suspensions may be used as standards. These may be obtained commercially or prepared according to the following procedure: Fill a glass-stoppered pyrex reagent bottle of 1-liter capacity to about one-fourth its capacity with fragments of clean pyrex glass. Cover the glass fragments with distilled water and agitate vigorously on a mechanical shaker until a milky suspension is produced; 8 to 20 hours is ordinarily sufficient. Decant the suspended glass into a 1000 ml. cylinder and dilute to the mark with distilled water. Mix and allow to stand 14 days. Decant the upper 500 ml. for use as a stock standard.

**Standardization.** For this operation a Beckman Model DU spectrophotometer is satisfactory; other instruments of comparable quality should serve as well. Make a trial reading of stock standard in the spectrophotometer at a wavelength of 660 m $\mu$  in a 10-mm. cuvette, using water as a blank. Add sufficient water to an aliquot of the stock standard to make the absorbancy of the mixed diluted suspension approximately 0.100. Now measure the exact absorbancy of the diluted suspension. An absorbancy of 0.100 has been found to be equivalent to 3.3 Maclagan units and 6.5 Shank-Hoagland units in the Evelyn photoelectric colorimeter with a 660 m $\mu$  filter, 6 ml. aperture, and standard reflector. Thus, in the calculation of results, where  $S = 0.100$ ,  $C = 3.3$  (Maclagan) or 6.5 (Shank-Hoagland). If  $S$  is slightly above or below 0.100, the appropriate value for  $C$  may be calculated by direct proportion. For colorimeters other than the Evelyn instrument, it is advisable to standard-

ml. of serum from a pipet that will deliver accurately between marks. (Do not blow out the pipet.) Stopper the cuvette and mix well. In 30 minutes measure the absorbancy (optical density, see p. 513) at 660  $m\mu$ , using thymol-barbital solution for the zero setting. If the thymol turbidity exceeds 20 units (see below), repeat using 0.05 ml. of serum. Multiply the result by 2 when this is done.

CALCULATION. Thymol turbidity units =  $U \times \frac{C}{S}$  where  $U$  is the absorbancy of the unknown,  $S$  of the glass standard, and  $C$  is the thymol turbidity equivalent of the standard.

For visual measurement, the egg albumin-gelatin-formazine standards of Kingsbury *et al.*, developed for the determination of protein in urine (see p. 929) were originally used by Maclagan. Comparison against these standards should be made with light coming from behind the observer. Calculate results by dividing the protein equivalent of the standard most closely matching the unknown by 60 to give Maclagan units and by 30 to give Shank-Hoagland units.

**Thymol Flocculation.** Decant the turbid solution into a conical centrifuge tube of 15 ml. capacity. Stopper and replace in the water bath at 25° C. until the following day. Examine the solution for the presence of a flocculum and note also the extent to which the supernatant fluid has cleared. Flocculation is graded on a scale from 4+ (water clear) to 1+ (flocculation and clearing are minimal).

**Interpretation:** a. THYMOL TURBIDITY. Results may be expressed either as Maclagan units or as Shank-Hoagland units. One Maclagan unit equals two Shank-Hoagland units. The Commission on Liver Disease of the Armed Forces Epidemiological Board has recommended that Shank-Hoagland units be adopted in preference to Maclagan units. Ninety-five per cent of a group of healthy subjects tested by Reinhold and associates were found to have thymol turbidities not exceeding 5.5 Shank-Hoagland units, and 99 per cent were below 6.6 units, using the procedure described here.

The thymol turbidity test is among the tests most frequently positive in virus hepatitis, and is particularly useful during the recovery period for evaluation of progress and for detection of carriers of viral hepatitis. Although patients with cirrhosis may show elevated thymol turbidity, it may fail to become positive in cirrhosis either of the Laennec or biliary type.

The thymol turbidity value is consistently within the limits of normal in biliary obstruction of recent origin; older lesions may occasionally result in abnormal values. Since the reagent also reacts with serum lipides, blood should be obtained from the patient in the postabsorptive state, and confirmatory evidence sought when serum lipides are elevated. Thymol turbidity may also be increased in any disease characterized by an elevated serum  $\gamma$ -globulin content, quite independently of liver involvement; such conditions include multiple myeloma, lymphogranuloma, sarcoidosis, parasitic infections, and others. While the liver may also be involved, proof can only be obtained by recourse to other liver-function tests not directly dependent upon changes in serum protein content.

---

ize the glass standard against a serum of known thymol turbidity. The glass standard deteriorates slowly but may be used for many months if protected from contamination.

b. **THYMOL FLOCCULATION.** Clinical experience suggests that the occurrence of flocculation depends upon some additional or different factors than does the production of turbidity.<sup>149</sup> In general, the significance of a positive flocculation test is the same as for abnormal turbidity. The flocculation test is less frequently positive than is the turbidity test; however, false positive tests are uncommon and the occurrence of thymol flocculation thus may be accepted with a higher degree of confidence as evidence of liver damage. The serum of healthy individuals shows no flocculation. Flocculation graded 1+ or more, therefore, is abnormal.

## CEPHALIN-CHOLESTEROL FLOCCULATION TEST

**Principle.** Suitably diluted serum of patients suffering from liver disease forms a flocculent precipitate when treated with a suspension of cephalin and cholesterol in water.<sup>150</sup> The mechanism of the reaction differs somewhat from that of the thymol turbidity test; the change in serum responsible for the test appears to be primarily in the albumin fraction.<sup>151</sup>

**Procedure.**<sup>152</sup> It is advantageous to use conical centrifuge tubes of 15 ml. capacity. Measure into such a tube 4 ml. of 0.85 per cent sodium chloride solution. Add 0.2 ml. of serum and mix well by tapping the tube vigorously 5 times. Add 1 ml. of cephalin-cholesterol reagent and again mix by tapping the tube vigorously at least 15 times. Place the tube in a water bath at approximately 25° C., in the dark and away from chemical fumes, until the following day. Examine the tube for presence of flocculation after 24 hours and again after 48 hours (optional).

Grade the reaction as 1+ to 4+ as described under "Thymol Flocculation" (p. 596) taking into account the amount of precipitate and the transparency of the supernatant fluid. If desired, the precipitate can be removed by centrifugation, the supernatant fluid decanted, and its absorbancy measured in a

---

<sup>149</sup> Neeffe: *Gastroenterology*, **7**, 1 (1946).

<sup>150</sup> Hanger: *J. Clin. Invest.*, **18**, 261 (1939).

<sup>151</sup> Moore, Pierson, Hanger, and Moore: *J. Clin. Invest.*, **27**, 737 (1948).

<sup>152</sup> Reagents Required: *Cephalin-Cholesterol Stock Solution*. The purchase of the reagent ("antigen") is recommended (Difco and Wilson brands are satisfactory). It is supplied in vials containing 100 mg. of cephalin, prepared from brain and aged, and 300 mg. of cholesterol. The contents of a vial are dissolved according to directions in U.S.P. ethyl ether, after addition of 1 drop of distilled water. The stock solution so obtained may be kept for several months if refrigerated and tightly stoppered.

*Cephalin-Cholesterol Reagent*. Measure 32 ml. of water into an Erlenmeyer flask of 50 ml. capacity with a mark scratched on it to indicate 27 ml. Place the flask on a water bath on an electric heater and heat to 65° or 70° C. While the water in the flask is kept at this temperature, add drop by drop 1 ml. of the stock cephalin-cholesterol solution, rotating the flask at the same time. Place the flask directly on the hot plate at low heat and boil gently to remove the ether until the volume is reduced to 27 ml. When cool, add 3 ml. of merthiolate solution, aqueous 1:1000, as a preservative. This reagent retains its activity unchanged for at least a week if stored in a refrigerator.

**Precautions.** Preparations of the cephalin-cholesterol reagent as purchased or prepared have been found to vary widely in sensitivity. Each lot of reagent must be assayed by testing serum of healthy individuals and of a sampling of patients showing positive reactions. Acceptable reagents do not produce more than an occasional 1+ flocculation when the sera of healthy subjects are tested, and on the other hand yield a high proportion of positive flocculations in patients suffering from liver disease. Once a suitable reagent has been obtained, new lots can be tested by comparing them with previous ones. For best results, tests should be done in duplicate, using two different preparations. Difficulties of standardizing and of controlling this test make it practical only when a considerable flow of samples through the laboratory may be expected.

photometer at 660  $m\mu$ , using a tube containing sodium chloride solution and reagent, but without serum, as a blank.<sup>153</sup>

**Interpretation.** With properly prepared reagents, reactions of 2+ or greater offer evidence of disturbed liver function. Hanger believes that a positive test is an indication of active parenchymal disease; in support of this may be cited the high proportion of patients suffering from acute viral hepatitis who exhibit positive cephalin-cholesterol flocculation. Positive tests occur within a few days of onset of clinical illness, frequently before jaundice or significant elevation of bilirubin appears, thus offering valuable support for a diagnosis of viral hepatitis, particularly in hepatitis without jaundice. However, failure of the cephalin-cholesterol test to become abnormal does not exclude the diagnosis. In one study, 20 per cent of a large group of patients ill of viral hepatitis gave negative tests.<sup>154</sup> Abnormal cephalin-cholesterol flocculation readings may or may not persist into the stage of recovery. In this respect the test differs from the thymol test, which tends to remain positive for a considerable time.

A high proportion of positive tests is found in cirrhosis. Positive tests are prevalent in a variety of diseases such as malaria, pneumonia, infectious mononucleosis, and others causing damage to the liver. Biliary obstruction of short duration is characterized by negative cephalin-cholesterol flocculations, and the test may be used along with other observations to aid in determining whether jaundice is due to surgically remediable causes. Inflammatory disease of the bile ducts usually is accompanied by a positive test.

### BROMSULFALEIN TEST<sup>155</sup>

**Principle.** A measured amount of bromsulfalein is injected intravenously. The liver rapidly removes the dye from its combination with plasma proteins and excretes it into the bile. If liver function is impaired, excretion is delayed and a larger proportion of the dye remains in the circulation. The dye concentration in serum is measured after addition of alkali to convert any dye present into its intensely colored sodium salt. Corrections are made for interference by turbidity and pigmentation of the serum.

**Procedure:**<sup>156</sup> PREPARATION OF PATIENTS, INJECTION OF DYE, AND COLLECTION OF BLOOD. The test is best done in the morning. The evening meal of the previous

<sup>153</sup> Kibrick, Rodgers, and Skupp: *Am. J. Clin. Path.*, 22, 698 (1952).

<sup>154</sup> Neefe, Gambesia, Gardner, and Knowlton: *Am. J. Med.*, 5, 600 (1950).

<sup>155</sup> Reinhold and Hutchinson: Unpublished.

<sup>156</sup> Solutions: *Sodium hydroxide solution.* Approximately 0.5 N and 0.05 N. The 0.05 N solution is prepared from 0.5 N by diluting tenfold with water.

*Phenol Tetrabromosulfonphthalein Sulfonate Sodium (Bromsulfalein) Standard Solution.* Transfer 50 mg. to a 500 ml. volumetric flask. Add 250 ml. of the 0.05 N sodium hydroxide solution and dilute to volume with water. (If crystalline bromsulfalein is not available, substitute 1 ml. of 5 per cent solution from an ampoule.) The standard solution so prepared contains 10 mg. in 100 ml. and is equivalent to 100 per cent retention of dye when 5 mg. per kg. is injected. (It is assumed that plasma volume represents 5 per cent of the body weight.) This standard is further diluted by measuring 10, 25, and 50 ml. aliquots and diluting them to 100 ml. with 0.05 N sodium hydroxide. The resulting standard solutions are equivalent to 1.0, 2.5, and 5.0 mg. per 100 ml. and represent 10, 25, and 50 per cent of the initial dye concentration. The standards remain unchanged over long periods. For actual measurement 0.5 ml. of each working standard is diluted to 6 ml. with 0.05 N sodium hydroxide.

*Apparatus:* A photoelectric photometer is preferred, to permit accurate measurement of

day should not include foods rich in fat. A breakfast of unbuttered toast and coffee, tea (without cream), or fruit juice is permissible, after which the patient should not eat until the test has been completed.

The quantity of bromsulfalein required is calculated according to the patient's ideal weight. The accompanying table shows the volume of 5 per

cent solution needed. This volume is introduced into a sterile syringe which is made ready for the injection.

A vein is entered and about 5 ml. of blood withdrawn. This blood is used as a control specimen if necessary. The syringe containing dye is then attached to the needle and the dye injected slowly over a 3-minute period. Forty-five minutes later about 5 ml. of blood is collected from a vein of the *opposite*

borderline retention and to permit correction for interference from hemoglobin. However, approximate measurements can be made by means of visual comparators. When the latter are used, additional standard solutions are prepared so as to give concentration intervals of 0.5 mg. up to 3.0 mg. and at 1.0 mg. intervals above this.

*arm* by means of a different syringe and needle. The exact time of completing the injection and of collecting the blood should be noted. The blood is allowed to clot, and serum is removed for analysis. Care is used to avoid hemolysis. Needle and syringe should be dry, and the blood should be transferred from syringe to tube gently and without production of foam.

**MEASUREMENT OF DYE CONCENTRATION.** Measure 0.5 ml. of the serum of the dyed specimen into a cuvette containing 5.0 ml. of water. Add 0.5 ml. of 0.5 N sodium hydroxide solution. Mix well and measure the absorbancy (optical density) at 660, 565, and 420  $m\mu$ , using water for the zero settings at each wavelength. Maximum absorption occurs at 580  $m\mu$  and this wavelength setting is theoretically to be preferred; however, interference from hemoglobin is less marked at 565  $m\mu$ . If serum bilirubin is elevated, the control sample is diluted and absorbancy measured as described for the dyed sample. The figures so obtained are subtracted from those of the bromsulfalein-containing serum. Calculate results as described below.

**CALCULATION:** Bromsulfalein, mg. per 100 ml. =  $f \times (U_{565} - 1.28 U_{660}) - 0.15 \times (U_{420} - 1.95 U_{660})$ . The values for  $U_{565}$ ,  $U_{660}$ , and  $U_{420}$  represent absorbancies of the diluted serum at the wavelengths of the subscripts.<sup>157</sup> The value for  $f$  is obtained as follows: determine the absorbancy,  $S$ , for each of the three standards (representing 1.0, 2.5, and 5.0 mg. per 100 ml.) at 565  $m\mu$ . Calculate  $f$  as follows:

$$f = \frac{C}{S_{565}}$$

where  $C$  is the concentration of standard and  $S_{565}$  is the absorbancy. Average the values to give the value of  $f$  used in the calculation. Once  $f$  has been determined, standards can be dispensed with except for occasional instrument checks. From the bromsulfalein content of the serum, the per cent retention is calculated as follows:

$$\text{Per cent retention} = \text{bromsulfalein, in mg. per 100 ml.} \times 10$$

A correction is applied in the method described to compensate for the presence of hemoglobin in serum, since hemolysis of some erythrocytes may be difficult to avoid and hemoglobin will cause falsely high readings even at 565  $m\mu$ . The effect of lactescence in serum is eliminated by making the absorbancy measurement at 660  $m\mu$ , where neither bromsulfalein nor hemoglobin absorb light. A correction may be used when the test is applied to jaundiced patients.<sup>158</sup>

Rosenthal and White used 2 mg. of dye per kg. of body weight. The 5 mg. per kg. dosage, however, has been adopted widely and provides a more sensitive and more

<sup>157</sup> The correction factors given in the calculation were calculated from readings with an Evelyn photocolormeter (see p. 526). They may be applied to readings made with other photometers provided the transmittancies at the wavelengths used do not differ greatly from those obtained with the Evelyn instrument. If desired, the factors may be determined by measuring the absorbancy  $A$  of a dilute solution of hemoglobin containing roughly 10 to 20 mg. hemoglobin per 100 ml. at 420 and 565  $m\mu$ . The correction for hemolysis is calculated by means of the ratio  $A_{565}/A_{420}$  obtained from the readings of the hemoglobin solution. This corresponds to the factor 0.15 in the calculation. The turbidity correction is based on readings of a colloidal glass suspension, similar to that described under thymol turbidity (see p. 595), made at 420, 565, and 660  $m\mu$ . Although turbid solutions have no absorption bands, their absorbancy increases progressively from the red to the blue regions of the spectrum. Therefore, the ratio  $A_{565}/A_{660}$  of the glass suspension represents the factor by which any measurements made at 660  $m\mu$  must be multiplied, and  $A_{420}/A_{660}$  the corresponding factor for the reading at 420  $m\mu$  in order to correct for turbidity. In the calculation above, these ratios are 1.28 and 1.95 respectively. The turbidity correction will vary with particle size and therefore represents an approximation. No corrections need be applied to the standards.

<sup>158</sup> Zieve, Hanson, and Hill: *J. Lab. Clin. Med.*, 37, 40 (1951).

precise test. The existence of an enterohepatic circulation of bromsulfalein<sup>159</sup> does not appear to influence the results sufficiently to necessitate a return to the original dosage.<sup>160</sup> The time at which the postinjection blood specimen is collected is not of great importance, provided that appropriate normal standards for that time are used; the 45-minute sampling time has proved to be satisfactory.

**Interpretation.** Healthy individuals, after injection of 5 mg. bromsulfalein per kg. of body weight, retain less than 10 per cent at 30 minutes and 7.0 per cent at 45 minutes. At 60 minutes, no dye is retained.

Bromsulfalein retention is generally accepted as the most sensitive and dependable among the laboratory procedures currently used to demonstrate involvement of the liver. It is especially helpful for evaluating suspicious or positive results obtained by means of flocculation tests in the absence of hyperbilirubinemia. The bromsulfalein test outranks all others in the proportion of positive tests found in Laennec's cirrhosis. It has been among the most useful for following recovery from virus hepatitis and for detecting residual liver damage from this disease. It is probably the only procedure capable of detecting fatty liver, although it cannot be depended upon to do so consistently.

For the study of the jaundiced patient the bromsulfalein test has little to offer. Maximal retention occurs in the presence of severe liver damage, and further deterioration of the liver function can have no additional effect on dye retention. Thus it is rarely used when hyperbilirubinemia or clinical jaundice are present.

## DETERMINATION OF PLASMA PROTEINS

**Introduction.** The standard method for the determination of protein is by the Kjeldahl type of digestion and oxidation, converting the nitrogen present to the form of ammonia, which is then determined. If the material contains nonprotein nitrogen, this is determined in a separate analysis and subtracted from the total nitrogen value to give the protein nitrogen. This is then multiplied by 6.25 to give the protein value, since the average protein contains 16 per cent nitrogen. If sufficient material is available the most accurate version of this procedure is a macro-Kjeldahl method similar to that described in Chapter 31 for the determination of the total nitrogen of the urine. For blood analysis with its inherent limitation in the amount of material available, this is replaced by the various micro-Kjeldahl methods, and the procedures become similar to the determination of nonprotein nitrogen already described (p. 545).

To obtain satisfactory results more rapidly and simply than is possible by micro-Kjeldahl methods, various direct colorimetric, turbidimetric, and specific gravity procedures have been developed. The colorimetric procedures are usually based on color reactions specific for protein or constituent amino acids and are standardized accordingly. Turbidimetric methods rely on the comparison of the turbidity produced by precipitating reagents on proteins in dilute solution with the turbidity produced similarly on a standard protein solution. The specific gravity methods

<sup>159</sup> Lorber and Shay: *Gastroenterology*, **20**, 262 (1952).

<sup>160</sup> Owen: *J. Lab. Clin. Med.*, **38**, 583 (1951).

are based on the fact that protein is by far the most abundant solid constituent of blood, and hence the specific gravity should be determined largely by the protein content.

Fractionation of the plasma proteins prior to separate analysis is based almost entirely on the classical methods using concentrated salt solutions, and the bulk of clinical literature is in terms of such fractions. Fractionation by electrophoretic mobility has not yet reached the stage of routine practicality, except possibly in a few of the larger institutions. For a further discussion of the various methods of fractionating the plasma proteins, see Chapter 22. The determination of blood hemoglobin content will be considered in a separate section.

**1. Micro-Kjeldahl Method:**<sup>161</sup> **Principle.** *Total proteins* are determined in serum or plasma by a micro-Kjeldahl method employing direct nesslerization, making the appropriate correction for nonprotein nitrogen. *Fibrinogen* in plasma is determined by isolation as fibrin, followed by digestion and direct nesslerization. *Albumin* is determined by analysis of the fluid remaining after precipitating the globulin fraction with 23 per cent sodium sulfate solution. *Globulin* in serum is estimated by subtracting the albumin from the total protein content; in plasma by subtracting albumin and fibrinogen from total protein.

**Procedure:**<sup>162</sup> **Total Proteins** (*Albumin + Globulin + Fibrinogen*). Dilute exactly 1 ml. of the serum or plasma to 50 ml. in a volumetric flask with 0.9 per cent sodium chloride solution. (If serum is used, the "total protein" will

---

<sup>161</sup> This method is a combined adaptation of the procedures of various authors. The direct nesslerization micro-Kjeldahl procedure of Wong (*J. Biol. Chem.*, **55**, 427 (1923)), employing persulfate for oxidation, is recommended because of its superiority when protein is present. Fractionation of the proteins with sodium sulfate solution follows the procedure of Howe (*J. Biol. Chem.*, **49**, 109 (1921)); this method is significantly improved by the use of ether to aid in separating the albumin and globulin fractions, as suggested by Kingsley (*J. Biol. Chem.*, **133**, 731 (1940)). Isolation of fibrinogen as fibrin is essentially according to Cullen and Van Slyke (*J. Biol. Chem.*, **41**, 587 (1920)). These latter authors point out the desirability of using a uniform amount of anticoagulant such as oxalate in comparative studies on plasma proteins, because of the effect of oxalate on water distribution between cells and plasma. They use 5 mg. of potassium oxalate per ml. of blood. For other methods of digestion and fractionation see Campbell and Hanna: *J. Biol. Chem.*, **119**, 1, 9, 15 (1937); Pillemer and Hutchinson: *ibid.*, **158**, 299 (1945). These latter authors use cold methyl alcohol for fractionation and claim their fractions agree closely with those obtained by electrophoretic separation.

<sup>162</sup> Reagents Required: **0.9 Per Cent Sodium Chloride Solution.** Dissolve 9 g. of reagent-grade low-nitrogen sodium chloride in water, dilute to 1 liter, and mix. Stable indefinitely.

**2.5 Per Cent Calcium Chloride Solution.** Dissolve 25 g. of anhydrous reagent-grade calcium chloride in water, dilute to 1 liter, and mix. Stable indefinitely.

**23 Per Cent Sodium Sulfate Solution.** Dissolve 230 g. of anhydrous reagent-grade sodium sulfate in 600–700 ml. of water by warming and stirring. While still warm transfer to a 1-liter volumetric flask, dilute with water to the mark, and mix. Transfer to a clean bottle and place in the incubator or water bath at 37° C. Keep at this temperature at all times, stoppered to prevent evaporation, since some of the salt will crystallize out if kept at room temperature.

**1:1 Sulfuric Acid.** Pour slowly and with stirring 1 volume of concentrated sulfuric acid into 1 volume of water. Cool, and keep stoppered to prevent absorption of ammonia from the air.

**Persulfate Solution.** Shake about 8 g. of reagent-grade nitrogen-free potassium persulfate in a glass-stoppered bottle with about 100 ml. of water. The undissolved excess settles to the bottom and helps keep the solution saturated even though there is gradual decomposition. Keep in the refrigerator, shake briefly and allow to settle before using, and prepare fresh every few weeks.

**Standard Nitrogen Solution and Nessler Reagent.** See p. 545.

represent only albumin + globulin.) Using 1 ml. of this diluted mixture, proceed as directed below under "Digestion."

**Fibrinogen.** To 1 ml. of plasma in a small cylinder add 30 ml. of 0.9 per cent sodium chloride solution, followed by 1 ml. of 2.5 per cent calcium chloride solution. Mix with a slender pointed glass rod, leaving the rod in the mixture. Allow to stand for 30 minutes or until a solid clot has formed. Carefully rotate the rod in the jelly, squeezing out the water by pressing the clot against the side of the cylinder at the same time. All the fibrin should stick to the rod and appear ultimately as a thin white sheath over the rod. If any bits of clot escape this process, pour the cylinder contents onto a dry filter, and when the fluid has drained pick up the remaining clots with the tip of the rod and squeeze out the excess fluid by pressing against the side of the funnel. Transfer the rod and adhering fibrin to a piece of dry filter paper and dry as thoroughly as possible by rolling against the filter paper. Transfer the rod and dried fibrin to a centrifuge tube graduated at 10 ml. and containing 4 ml. of 1 per cent sodium hydroxide solution. Place tube and contents in a boiling water bath until the fibrin has dissolved and only a turbid suspension of calcium oxalate remains. This should require but a few minutes. Remove from the water bath, remove the rod, washing it down with a few ml. of water, and make up the contents of the tube to 10 ml. with water. Mix and centrifuge. Pipet a 5-ml. portion of the clear supernatant fluid to a digestion tube and proceed as described below under "Digestion."

**Albumin.** To 1 ml. of serum or plasma in a 50-ml. centrifuge tube add exactly 30 ml. of 23 per cent sodium sulfate solution. Stopper and mix by inversion. Add about 5 to 10 ml. of ether, again stopper, and shake vigorously. Centrifuge for about 10 minutes, capping the tube to prevent loss of ether. After centrifuging, the precipitated globulins should form a compact layer below the ether and above the clear albumin solution.<sup>163</sup> Slant the tube and insert a pipet of narrow bore, and with the mouthpiece closed by the finger, along the side of the tube past the packed globulin layer into the clear fluid below. Fill the pipet with the fluid and transfer to a dry test tube, wiping off any precipitate adhering to the outside of the pipet before discharging its contents. Use 1 ml. of this for digestion as described below. If a centrifuge is not available, the mixture may be poured onto a retentive filter (such as Whatman No. 50) and covered with a watch glass to prevent evaporation. If the first portions of filtrate are not clear, return to the filter. Use 1 ml. of the clear filtrate.

**Digestion.** Into a pyrex test tube graduated at 35 and 50 ml. (see method for nonprotein nitrogen, p. 545) place 1 ml. (or 5 ml. in the case of fibrinogen) of the solution to be analyzed. Add 1 ml. of 1:1 sulfuric acid and a quartz chip or a few glass beads. Digest over a microburner as described for the determination of nonprotein nitrogen until excess water has been driven off, the solution darkens, and white fumes appear. When the tube is nearly full of dense fumes, cover the mouth of the tube with a watch glass and reduce the flame or raise the tube so that the mixture boils gently. Continue boiling for 3 minutes. Remove the burner and allow to cool for 1 minute. Add to the tube contents, drop by drop, 0.5 ml. of persulfate solution. Replace the burner, tap the tube to start boiling if necessary, and con-

<sup>163</sup> On cold days some of the sodium sulfate may crystallize out during the centrifuging. If this happens, warm the tube and contents in the incubator at 37° C. until the crystals have redissolved, add more ether, shake, and again centrifuge as described.

tinue boiling until clear. Cool, dilute with water, and proceed with the direct nesslerization and colorimetric or photometric measurement exactly as described on p. 546 for the determination of nonprotein nitrogen. The same standard is used, containing 0.15 mg. of nitrogen, in the presence of 1 ml. of the 1:1 sulfuric acid and 0.5 ml. of persulfate solution, to balance the amounts present in the unknown. For photometric measurement the blank tube contains water, acid, and persulfate as described for the standard.

**CALCULATION.** *For colorimetric measurement.*

*Total Protein and Albumin* are calculated directly, as follows:

$$\left[ \left( \frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.15 \times \frac{100}{V} \right) - \text{NPN} \right] \times \frac{6.25}{1000} \\ = \text{grams protein per 100 ml. (or per cent protein)}$$

where  $V$  represents the actual volume of serum or plasma used in the determination; NPN represents the nonprotein nitrogen content in mg. per cent, as determined in a separate analysis. For total protein,  $V = 0.02$ ; for albumin,  $V = 0.0323$  (i.e.,  $\frac{1}{31}$ ).

*Fibrinogen* is calculated as follows:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.15 \times 2 \times 100 \times \frac{6.25}{1000} \\ = \text{grams fibrinogen per 100 ml. of plasma}$$

*Globulin* = Total Protein - (Albumin + Fibrinogen) in the case of plasma; for serum, *Globulin* = Total Protein - Albumin.

*For photometric measurement.* Calculations are the same except that the expression  $\frac{\text{Density of Unknown}}{\text{Density of Standard}}$  replaces the expression  $\frac{\text{Reading of Standard}}{\text{Reading of Unknown}}$  used in the colorimetric calculations. The limits of accurate colorimetric or photometric measurement are the same as those specified for the determination of nonprotein nitrogen on p. 547. If an analysis falls outside of these limits, the digestion is repeated, using a smaller or larger aliquot as the case may be, and the calculations are corrected accordingly.

**Interpretation.** Normal values for plasma proteins, in g. per 100 ml. of plasma, are as follows: albumin, 4.6–6.7; globulin, 1.2–2.3; fibrinogen, 0.3–0.6. A major function of the plasma proteins (see Chapter 22) is to aid in the normal distribution of water between the blood and tissues, albumin being approximately twice as effective as globulin in this respect, gram for gram. Edema almost invariably occurs when the total plasma proteins fall below the critical level of 5.3 g. per 100 ml. Increased plasma protein levels are noted in dehydration, due to diminished fluid intake or pathologic loss of fluid from the body (diarrhea, vomiting, surgical or traumatic shock, excessive burns, Addison's disease); or when there is an absolute increase in globulin content, as in various anaphylactic conditions, malignancy, liver cirrhosis, and certain chronic infections. Decreased plasma protein is found after loss of plasma by extravasation or renal excretion (albuminuria) or when protein synthesis is impaired owing to malnutrition, vitamin deficiencies, or diseases involving the digestive organs or liver. Fibrinogen values are increased in pneumonia and other infections accompanied by leukocytosis or suppuration, but are low in acute yellow atrophy of the liver, poisoning due to chloroform or phosphorus, and typhoid fever. High sedimentation rate of red blood cells is associated with increased fibrinogen values in plasma.

**2. Method of Kingsley:**<sup>164</sup> **Principle.** The diluted plasma or serum is treated with a special biuret reagent. The color developed is compared with that of a standard protein solution treated similarly. By suitable fractionation of serum before treatment with the biuret reagent, albumin may be determined separately. From the total serum protein and albumin contents, globulin is determined by difference. The method as described has been slightly modified to permit the determination of total protein, albumin, and globulin on the same sample of serum.

**Procedure.**<sup>165</sup> Transfer 0.5 ml. of unhemolyzed serum to a graduated centrifuge tube, or small (13 × 125 mm.) test tube graduated at 10 ml. Add 23 per cent sodium sulfate solution to the 10-ml. mark. Mix well by repeated inversion (but do not shake), and immediately pipet out a 2-ml. portion of the uniform suspension and place in a separate small test tube, which need not be graduated. This is Tube 1, which will be used for the determination of total protein. To the remainder of the suspension in the centrifuge tube add about 3 ml. of ether, stopper, and shake vigorously. Centrifuge for about 5 minutes, capping the tube to prevent loss of the ether. After centrifuging, hold the tube in a slanting position and insert the tip of a 2-ml. transfer pipet of narrow bore along the side of the tube past the white layer of packed globulin precipitate and into the clear fluid below. Remove a 2-ml. portion of the clear fluid with the pipet, wipe off any precipitate adhering to the outside of the pipet, and transfer to a second test tube (Tube 2). This will be used for the

<sup>164</sup> Kingsley: *J. Lab. Clin. Med.*, 27, 840 (1942). See also Robinson and Hogden: *J. Biol. Chem.*, 135, 707, 727 (1940); Mehl: *ibid.*, 157, 173 (1945). An improved biuret reagent and procedure has been described by Weichselbaum: *Am. J. Clin. Pathol.*, 7, 40 (1946).

<sup>165</sup> Reagents Required: *23 Per Cent Sodium Sulfate Solution.* Dissolve 230 g. of anhydrous reagent-grade sodium sulfate in 600 to 700 ml. of water in a beaker by heating and stirring. While still warm transfer to a 1-liter volumetric flask, dilute with water to the mark, and mix. Transfer to a clean bottle, and place in the incubator or water bath at 37° C. Keep at this temperature at all times, stoppered to prevent evaporation, since some of the salt will crystallize out if kept at room temperature.

*Special Biuret Reagent.* Prepare a saturated solution of sodium hydroxide which is carbonate-free (see Appendix). This saturated solution should contain about 75 g. of sodium hydroxide per 100 ml. after preparation. This may be checked by titration of a diluted portion. Measure 92 ml. of the carbonate-free saturated solution of sodium hydroxide, containing 69 g. of sodium hydroxide, into a 500-ml. graduated cylinder, and add water to the 300-ml. mark. Add 100 ml. of a 1 per cent solution of crystalline copper sulfate, and stir to mix. Transfer to a clean bottle fitted with a rubber stopper. This reagent is stable for months at room temperature. The formation of a slight sediment does not appear to impair its usefulness, particularly in photometric measurements run with a blank and standard as described in the text.

*Standard Protein Solution.* Obtain a pooled lot of normal human serum (10–15 ml. will be needed). Determine the total protein content of a portion by micro-Kjeldahl or macro-Kjeldahl analysis (see p. 601). Dilute 5 ml. of the remainder to 100 ml. in a volumetric flask with 15 per cent sodium chloride solution, and mix. Label with the total protein content, in grams per 100 ml., of the original serum, since this value is used in the calculations. This solution is usable for about a month if kept in the refrigerator at all times. A new solution may be standardized by colorimetric comparison with the previous standard if deterioration of the latter has not occurred. If this procedure is followed, check occasionally by the Kjeldahl method to avoid the possibility of error. Since with a particular photometer the density of a given standard is quite constant if the analysis is properly carried out, this is as good an index as any of possible changes in the standard.

For colorimetric measurement, three colored standards are prepared, representing the biuret reaction on sera at a level of approximately 3, 6, and 9 g. per cent total protein respectively. These standards are stable for at least one month if stored in the refrigerator. *Standard I.* To 1 ml. of serum of known protein content add 39 ml. of water and 80 ml. of the biuret reagent. *Standard II.* To 2 ml. of the serum add 38 ml. of water and 80 ml. of biuret reagent. *Standard III.* To 3 ml. of serum add 37 ml. of water and 80 ml. of biuret reagent. The equivalent protein values for these standards, used in the calculation, are as follows: Standard I,  $C/2$ ; Standard II,  $C$ ; Standard III,  $3C/2$ ; where  $C$  is the total protein content of the serum used, in grams per 100 ml.

albumin determination. For photometric measurement, place 2 ml. of the standard protein solution in a third tube, and 2 ml. of water alone in a fourth tube as a blank. For colorimetric measurement these latter two tubes are unnecessary since the unknown is compared against standards which have already been prepared (see below and footnote 165). To each tube add 4 ml. of the special biuret reagent, followed by 2 to 3 ml. of ether. Stopper, shake vigorously, and centrifuge for 5 minutes. By means of a pipet, transfer the solution under the ether layer to colorimeter cups or photometer cuvettes<sup>166</sup> and read within the next 10 to 20 minutes, preferably as soon as possible, since on prolonged standing a slight turbidity may develop which requires further treatment with ether and centrifugation. For photometric measurement, set the photometer to zero density with the blank, at 520 m $\mu$ .

If the total protein content alone is desired, the fractionation with sodium sulfate solution is omitted. Dilute 0.5 ml. of serum to 10 ml. with 0.9 per cent sodium chloride solution, mix, transfer a 2-ml. portion to a small test tube, and continue as described for Tube 1 above. Alternatively, 0.1 ml. of serum, measured in a pipet calibrated "to contain," may be pipetted into 1.9 ml. of 0.9 per cent sodium chloride solution in a test tube, the pipet being rinsed several times with the diluting fluid, and this 2-ml. portion treated with biuret reagent as described above.

CALCULATION. *For colorimetric measurement*, use a green filter (with maximal transmission at 520 m $\mu$ ) over the eyepiece, set the unknown at 10 mm., and read against those two of the three standards described in footnote 165 which appear on inspection to be lower and higher respectively than the unknown. Calculate results as follows:

$$\frac{A \times \frac{R_L}{10} + B \times \frac{R_H}{10}}{2} = \text{grams protein per 100 ml.}$$

where  $A$  and  $B$  represent the equivalent protein concentrations of lower and higher standards respectively, in grams per 100 ml. of serum, and  $R_L$  and  $R_H$  are the respective standard readings. If the unknown reading is within 10 or 15 per cent of either standard, the comparison with the other standard may be omitted, in which case the calculation becomes:

$$\frac{\text{Reading of Standard}}{10} \times C \times f = \text{grams protein per 100 ml. of serum}$$

where  $C$  is the total protein concentration of the standard serum used, in grams per cent, and  $f$  is 0.5, 1.0, or 1.5 depending upon whether Standard I, II, or III is used.

Calculations for Tubes 1 and 2 are the same, the value for Tube 1 giving total protein in grams per cent, and the value for Tube 2 giving albumin in grams per cent. Globulin = Total protein - Albumin.

*For photometric measurement:*

*Total Protein.*

$$\frac{\text{Density of Tube 1}}{\text{Density of Standard}} \times C = \text{grams total protein per 100 ml. serum}$$

*Albumin.*

$$\frac{\text{Density of Tube 2}}{\text{Density of Standard}} \times C = \text{grams albumin per 100 ml. serum}$$

<sup>166</sup> If the photometer is equipped for use with small test tubes which can be centrifuged, these may be used for color development and subsequent reading, without the necessity for transfer.

*Globulin.*

Total protein — albumin = grams globulin per 100 ml. serum

$C$  is the total protein content of the (undiluted) standard serum, in grams per cent. At 520  $m\mu$ , and in a 1-cm. cuvette, a serum containing 7 g. per cent of total protein has a density of approximately 0.400, when corrected for the density of the blank (Fig. 157). Up to 11 g. per cent of total protein may be determined accurately under the conditions described. For higher values, or with deeper cuvettes, use 1-ml. portions instead of 2-ml. portions in Tubes 1 and 2, plus 1 ml. of water, and multiply the results by 2.

FIG. 157. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED IN KINGSLEY METHOD FOR PROTEIN.

For biuret reagent alone (*bl*), and for biuret reagent in presence of serum containing 3.5 g. per cent total protein (*a*), and 7 g. per cent total protein (*b*). Solution depth, 1 cm.

**Interpretation.** Values for most normal and pathological sera by this method show good agreement with micro-Kjeldahl determinations. Discrepancies have been noted under certain conditions, but it is not known whether this is due to alteration in nitrogen content or in biuret-reacting power. The method is known to give satisfactory clinical results. For further interpretation, see the preceding method.

### 3. Determination of Plasma or Serum Protein, Hemoglobin, and Cell Volume (Hematocrit) by the Copper Sulfate-Specific Gravity Method:<sup>167</sup>

**Principle.** The specific gravity of whole blood, plasma, or serum is established by allowing small drops of the material to fall into a series of copper sulfate solutions of known and varying specific gravity and noting whether the drops rise, fall, or remain suspended under the defined conditions. From the specific gravity thus established, the plasma or serum protein, hemoglobin, and hematocrit values are obtained on the basis of an experimentally established relationship between these various quantities. If the plasma or serum protein content alone is to be determined, only plasma or serum is needed. Approximate hemoglobin and hematocrit values (within about 10 per cent) may be obtained with a few drops of whole blood alone. Accurate hemoglobin and hematocrit values are obtained by determining the specific gravity of both whole blood and its plasma.

<sup>167</sup> As developed by Phillips, Van Slyke, Dole, Emerson, Hamilton, and Archibald, at the Hospital of the Rockefeller Institute for Medical Research. For a "gradient tube" method, based on a similar principle but using nonaqueous solvents in a single tube, and suitable for very small amounts of serum, see Lowry and Hunter: *J. Biol. Chem.*, **159**, 465 (1945).

**Procedure.** Venous blood is collected with a minimal amount of stasis (tourniquet applied for not over one minute). Capillary (finger tip) blood may be used, except in shock, for the approximate hemoglobin and hematocrit determination. To obtain plasma, transfer the blood immediately after drawing to a container having either a dried film of heparin sufficient to provide approximately 0.2 mg. for each ml. of blood expected, or a dried film of the Heller and Paul oxalate mixture<sup>168</sup> sufficient to provide not over 1 mg. per ml. of blood expected. Mix to dissolve, and centrifuge. If both whole blood and plasma are wanted, save a portion of the well-mixed blood for the whole-blood determination and centrifuge the remainder to obtain the plasma. For serum protein determination, serum from ordinary clotted blood is used.

Prepare a series of standard copper sulfate solutions of known and varying specific gravity.<sup>169</sup> For the most accurate work, the series should be graded at intervals of 0.001 in specific gravity; for rougher work, intervals of 0.004 suffice. For plasma and serum, the range of specific gravity covered should be 1.015 to 1.035; for whole blood, 1.035 to 1.075.

Allow a small drop of the sample to fall by gravity from a height of about 1 cm. above the solution (see Fig. 158) into one of the standard copper sulfate

FIG. 158. METHOD OF DROPPING BLOOD INTO COPPER SULFATE.

solutions having approximately the specific gravity expected. The smaller the drop the better; use a medicine dropper with a drawn-out tip, or a syringe needle. If the sample is whole oxalated or heparinized blood, the cells and plasma must be thoroughly mixed by repeated inversion immediately before use, otherwise serious error will result. Observe the behavior of the drop *within the 10-second period after it has lost the momentum of its fall*. If the drop rises at all during this period, it is lighter than the test solution; if it continues to fall, it is heavier; if it remains stationary after momentum is lost, it has the same specific gravity as the solution. After the 10-second period indicated, the behavior of the drop has no significance, because of changes in specific gravity due to diffusion through the copper proteinate film around the drop. If the specific gravity of the drop is not established exactly by the first test, repeat the procedure with a fresh drop on solutions of higher or lower specific gravity as the case may be, until a solution is found in which the drop either remains stationary, which gives the specific gravity of the sample, or there are two adjacent stand-

ards in one of which the drop rises, and in the other it falls. In this case interpolation between the values of the two standards is used; by noting the relative rate of rise and fall in the two solutions, it should be possible to interpolate to one-quarter of the difference in specific gravities between them. Thus by experience one should be able to tell whether the specific gravity of the drop is halfway between the two standards, or nearer to one than to the other.

<sup>168</sup> Dissolve 3 g. of ammonium oxalate and 2 g. of potassium oxalate in water and dilute to 250 ml. Pipet 0.05 ml. of this solution for each ml. of blood to be received in a container (small test tube or bottle), spread in a film and dry in an incubator at 37° C. or in a vacuum desiccator. See Heller and Paul: *J. Lab. Clin. Med.*, 19, 777 (1934).

<sup>169</sup> See Appendix.

If oxalated whole blood and plasma are used, correct the observed values for the oxalate by subtracting 0.0004 for each mg. of oxalate mixture present per ml. of blood, applying the correction to both whole blood and plasma results. Heparinized blood or serum requires no correction. Use the corrected values in obtaining results.

CALCULATION. From the determined specific gravities, results are obtained by reference to the line chart shown in Fig. 159. For approximate hemoglobin and hematocrit

FIG. 159. LINE CHART FOR CALCULATING PLASMA PROTEINS, HEMOGLOBIN, AND HEMATOCRIT FROM SPECIFIC GRAVITIES OF PLASMA AND BLOOD.

determination using whole blood alone, the blood is assumed to have a normal plasma specific gravity of 1.0264, and a line from this point on the left-hand scale of the chart is drawn across the chart to the determined whole blood specific gravity as measured on the right-hand scale. The hemoglobin content and hematocrit value are read from the interception of this line with the middle scale. Where both plasma and whole-blood specific gravities have been determined, the line is drawn connecting the two measured values on their respective scales, and the hemoglobin and hematocrit values read from the intercept on the middle scale. For plasma protein content, in grams per 100 ml., the left-hand scale is used. If serum is used instead of plasma, the same scale is used, the results then being in terms of grams of protein per 100 ml. of serum.

The copper sulfate solutions are permanent if kept stoppered to prevent evaporation. A given standard may be used over and over again, until one-fortieth its volume of blood, plasma, or serum has been added, i.e., one small drop per ml. Thus a 100-ml. portion serves for about 100 tests. For routine work, it is good practice to keep a record of the number of drops added to a given standard, and to discard it when the indicated limit has been reached. The solutions are self-cleaning, precipitated material ordinarily settling to the bottom. If any material should stick in the surface film, either during or after an analysis, it should be dislodged by tapping or removed with a wooden applicator stick before further use. The hemoglobin of whole blood will impart a greenish color to used standards; this does not impair their effectiveness. Temperature control is necessary only in the preparation of the standards, as described in the Appendix; once the standards are prepared, further temperature control is ordinarily unnecessary.

**Interpretation.** See previous methods.

**Other Methods.** The micro-Kjeldahl method may be made more accurate by distillation followed by nesslerization or titration; gasometric determination of the ammonia may also be used. See discussion of non-protein nitrogen determination on p. 548. The colorimetric method of Greenberg<sup>170</sup> is described in the eleventh edition of this book. The determination of the specific gravity is the basis of the "falling drop" method of Barbour and Hamilton,<sup>171</sup> which has found considerable clinical application. For a turbidimetric method, see Looney and Walsh.<sup>172</sup>

## DETERMINATION OF HEMOGLOBIN

**Introduction.** In spite of the great clinical importance of hemoglobin determinations, as a rule they are the most poorly conducted of all blood chemical analyses. The majority of so-called office instruments in the hands of the average worker are known to give errors as high as 20 per cent. The very fact that a method is adapted for small amounts of blood should presuppose accurate calibration and use of pipets, careful dilution and color match, and frequent checking of both instrument and technician on blood of known hemoglobin content.

The standard method for the determination of hemoglobin, and the one upon which almost all others are ultimately based, is the determination by gasometric methods of the oxygen-binding power (*oxygen capacity*) of the blood. This method is described in detail in Chapter 24. An advan-

---

<sup>170</sup> Greenberg: *J. Biol. Chem.*, **82**, 545 (1929).

<sup>171</sup> Barbour and Hamilton: *J. Biol. Chem.*, **69**, 625 (1926).

<sup>172</sup> Looney and Walsh: *J. Biol. Chem.*, **130**, 635 (1939).

tage of this method is that when properly carried out the results represent the *functional* hemoglobin of the blood, or that portion which is capable of carrying oxygen,<sup>173</sup> and do not include such nonfunctional pigment as methemoglobin, carbon monoxide hemoglobin, etc., as is the case with most of the other common methods. Results by the oxygen capacity method may be expressed directly in terms of oxygen, as *volumes per cent*, i.e., ml. of bound oxygen per 100 ml. of blood, or they may be converted to grams of hemoglobin by making use of the empirically established fact that 1 g. of hemoglobin is capable of combining with 1.36 ml. of oxygen under optimal conditions.<sup>174</sup> Thus an oxygen capacity of 20 volumes per cent corresponds to a hemoglobin content of 20/1.36, or 14.7 g. per 100 ml.

Another method for the determination of hemoglobin which is also suitable for standardization purposes, particularly in laboratories where gasometric equipment is not available, is to determine the total iron content of the blood. The iron content of hemoglobin has been accurately established at 0.340 per cent,<sup>174</sup> and the hemoglobin iron ordinarily represents 98 per cent or more of the total blood iron. Thus if the iron content is determined, the hemoglobin content may be accurately established. A simple and reliable colorimetric procedure for this purpose, developed by Wong, is described elsewhere in this section.

Direct colorimetric procedures for hemoglobin determination range from the most simple to the most complex, with a corresponding range in accuracy. They utilize either the color of the blood itself (diluted or undiluted as the case may be) or the color produced by treating blood with various reagents. The color is compared with, or measured in terms of, a standard color obtained from or representing a blood of known hemoglobin content. These procedures are best used in conjunction with the ordinary laboratory colorimeter or photometer as described below. For clinical purposes, a number of special "hemoglobinometers" of various types have been designed. The Dare hemoglobinometer, one of the simplest of the clinical instruments, is based on comparison of a film of undiluted blood of uniform depth with a red glass plate of graduated intensity which has been suitably standardized. In the Spencer "Hb-Meter" (Fig. 160), the absorption of light by the hemoglobin in a layer of hemolyzed blood of fixed depth is compared with light absorption of a standardized glass wedge. The widely used Sahli type of clinical hemoglobinometer (Fig. 161), is based on treatment of the blood with dilute acid to produce the brown "acid hematin" color, followed by dilution until the color exactly matches a standard brown glass plate. From the

FIG. 160. AO SPENCER HB-METER.

Courtesy, American Optical Company, Buffalo, N. Y.

<sup>173</sup> The desirability of this distinction may be limited under certain conditions, as for example in methemoglobinemia. See also Rimington: *Ann. Rev. Biochem.*, 12, 430 (1943).

<sup>174</sup> Bernhart and Skeggs: *J. Biol. Chem.*, 147, 19 (1943).

dilution required, the hemoglobin content is readily obtained. This instrument is frequently very carelessly used; with care, however, it is capable of giving results accurate to within 5 per cent or so. The development of the photoelectric cell has produced hemoglobinometers of which the Fisher "Electro-hemometer" is an example (Fig. 162). This is essentially a one-purpose desk-model photoelectric photometer; the blood

FIG. 161. SAHLI HEMOGLOBINOMETER.  
Courtesy, Klett Manufacturing Co.

FIG. 162. FISHER ELECTRO-HEMOMETER.  
Courtesy, Fisher Scientific Co.

sample, appropriately diluted in the glass tube, is placed in the instrument and the hemoglobin content read directly from the scale, which is calibrated by the manufacturers.

For all hemoglobinometers supplied with a ready-made calibration, regardless of type or source, the desirability of checking the calibration at intervals with blood of known hemoglobin content cannot be overemphasized. Manufacturers do not use these instruments, they merely make them; and the conditions of calibration and use may vary from time to time and differ from laboratory to laboratory. Only by careful checking under the conditions of actual use is it possible to eliminate errors from this source.

It has been the custom among clinicians to express hemoglobin values in terms of per cent of some arbitrarily established normal. Unfortunately, there is no general agreement as to what the "normal" value should be, for the very good reason that the hemoglobin content of the blood of a normal individual depends upon such factors as age, sex, occupation, climate, altitude, and other environmental circumstances, etc., and is obviously also influenced by the red cell count of the blood and factors which cause normal variation in this respect. The confusion attendant to the use of "per cent of normal" is illustrated by the fact that a blood hemoglobin content of say 14.5 g. per 100 ml., which is an exact value,

becomes "105 per cent of normal" on the Haldane scale, where 13.8 g. per cent is considered normal, and "84 per cent of normal" on the original Sahli scale, which considered 17.3 g. per cent as normal. The logical way to avoid this confusion, and one which is finding increasing clinical favor, is to express blood hemoglobin content in terms of grams of hemoglobin per 100 ml. of blood, or volumes per cent oxygen capacity, whichever is preferred, without reference to any arbitrary "normal," interpreting the result if desired in terms of values obtained under similar circumstances from normal individuals of the same age and sex.

It is perhaps even more desirable to adjust the hemoglobin content to an arbitrary standard red cell count, usually 5,000,000. To illustrate, in their standardization of the copper sulfate-specific gravity method for hemoglobin and other blood proteins (p. 607), Phillips, Van Slyke, *et al.*, found the average oxygen capacity of 20 normal adult men to be 21.6 vols. per cent, corresponding to a hemoglobin content of 15.9 g. per cent. If the average red cell count under these conditions is 5.4 million, an acceptable value, the hemoglobin content on the basis of 5.0 million red cells will be  $15.9 \times 5.0/5.4$ , or 14.7 g. per cent.<sup>175</sup> In this connection, it is further of interest to note that while adult females have an apparent average hemoglobin content lower by about 1.0 g. per cent than adult males, this difference largely disappears if results are corrected for the variation in red cell count as described above.<sup>176</sup>

**1. "Acid Hematin" Method of Cohen and Smith:**<sup>177</sup> **Principle.** Blood is treated with dilute hydrochloric acid to produce a brown color ("acid hematin"). This is then compared with the color produced by similar treatment of a blood of known hemoglobin content.

**Procedure.**<sup>178</sup> Measure 0.05 ml. of blood from a freely flowing source into an accurate micropipet, calibrated "to contain." If the blood appears to be low in hemoglobin, it is advisable to use a double sample. Wipe off excess blood from the outside of the pipet, and blow the blood from the pipet into

<sup>175</sup> Haden's value on a 5.0 million red cell basis is 15.6 g. per cent (*J. Am. Med. Assoc.*, 79, 1496 (1922)). Dr. Ralph G. Stillman (personal communication) has summarized literature reports relative to 11 large cities throughout the world and finds an average value of 14.7 g. per cent computed in terms of a 5.0 million red cell count.

<sup>176</sup> Haden: *loc. cit.*

<sup>177</sup> Cohen and Smith: *J. Biol. Chem.*, 39, 489 (1919).

<sup>178</sup> Reagents Required: *Dilute Hydrochloric Acid.* Dilute 10 ml. of concentrated hydrochloric acid to 1 liter with water and mix. This solution is approximately 0.1 normal; it need not be standardized.

*Standard "Acid Hematin" Solution.* Obtain a large sample of normal human blood and determine its hemoglobin content by either gasometric methods (Chapter 24) or the iron method of Wong (p. 617). On the basis of the hemoglobin content, dilute the blood with 0.1 N hydrochloric acid in a volumetric flask so that the resultant hemoglobin concentration is

3 per cent. Thus if the hemoglobin content is 14.2 g. per cent, dilute 21.1 ml.  $\left(\text{i.e., } \frac{100 \times 3}{14.2}\right)$

to 100 ml. with 0.1 N acid. Mix well and store in the refrigerator. This stock standard will keep for three months if kept cold and away from light. It must be well-mixed just before using, because the brown color is due to a colloidal suspension of hemin, which will settle out on standing. From the stock solution, the dilute standard is prepared fresh every week by diluting 5 ml. to 200 ml. in a volumetric flask with 0.1 N acid. Keep cold and away from light, and mix well before using. This dilute standard is an "acid hematin" solution equivalent to 0.075 g. per cent hemoglobin (i.e., to 15 g. per cent blood hemoglobin at a 1:200 dilu-

10 ml. of dilute hydrochloric acid. Rinse the pipet thoroughly by sucking up the acid and blowing back several times. Allow to stand at room temperature for at least 1 hour to complete color development, or, if speed is essential, place in hot tap water (50 to 55° C.) for 10 minutes.<sup>179</sup> Read in the colorimeter or photometer against the standard "acid hematin" solution. For photometric measurement, set the photometer to zero density with water or dilute acid as a blank, at 520 m $\mu$ .

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.075 \times \frac{100}{0.05} \times \frac{10}{100} = \text{grams hemoglobin per 100 ml. blood}$$

In this calculation, the 0.075 represents the hemoglobin content of the standard, in g. per 100 ml.; the 0.05 is the volume of blood taken, and the 10 (more exactly 10.05) represents the volume to which the blood is diluted. If smaller or larger amounts of

FIG. 163. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED IN "ACID HEMATIN" METHOD FOR HEMOGLOBIN.

For (a) 7.5 g. per cent hemoglobin, and (b) 15 g. per cent hemoglobin, each at a 1:200 dilution. Solution depth, 1 cm.

blood are used, at the same or different dilution volumes, change the calculation accordingly. A blue glass or gelatin filter over the eyepiece of the colorimeter improves the precision of color match.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.075 \times \frac{100}{0.05} \times \frac{10}{100} = \text{grams hemoglobin per 100 ml. blood}$$

The "acid hematin" color, which is really a colloidal suspension of hemin (see Chapter 22), has no characteristic peak light absorption in the visible spectrum (Fig. 163).

tion). For a method of preparing standard "acid hematin" solutions from crystalline hemin, see Elvehjem: *J. Biol. Chem.*, 93, 203 (1931).

<sup>179</sup> If both unknown and standard are treated with one-tenth volume of 10 per cent sodium hydroxide at this point, after color development and prior to reading, the procedure becomes the "alkali hematin" method of Wu (*J. Biochemistry (Japan)*, 2, 173 (1922)), claimed to be superior to the "acid hematin" method. See, however, Ponder: *J. Biol. Chem.*, 144, 339 (1942). Conditions of color measurement and calculations are the same as for the procedure described in the text.

The choice of filter depends largely upon the sensitivity desired. At 520  $m\mu$ , and in a 1-cm. cuvette, the standard (equivalent to 15 g. per cent hemoglobin at a dilution of 1:200) has a density of approximately 0.500, and agreement with Beer's law is excellent over the entire range of hemoglobin content apt to be encountered.

This method has the advantage of a relatively permanent standard, in terms of which each unknown may be measured. It will probably be found that for a given photometer and filter or wavelength setting the density of the standard will be constant and reproducible from day to day if mechanical or other changes do not occur in the photometer and if measurements are made under uniform conditions. In this event, the established density of the standard may be used in the photometric calculations without the necessity of reading the standard at each analysis. To eliminate error due to any changes in calibration, however, it is advisable to check the standard reading at intervals.

**Interpretation.** The hemoglobin content as determined by either the "acid hematin" or "alkali hematin" methods represents *total hemoglobin*, i.e., the methods do not distinguish between hemoglobin itself and such nonfunctional derivatives as methemoglobin, carbon monoxide hemoglobin, etc. Thus the results are apt to be slightly high as compared to oxygen capacity measurements, particularly in the case of city dwellers and chronic tobacco smokers, whose blood may contain up to 5 per cent of its total hemoglobin as carbon monoxide hemoglobin. The "acid hematin" method as described is not applicable to the blood of species possessing nucleated erythrocytes (i.e., birds) because of the turbidity caused by the nuclei;<sup>180</sup> the "alkali hematin" method does not have this disadvantage.

In normal individuals, at birth the blood hemoglobin content may be over 21 g. per 100 ml. of blood, dropping to about half this value, or around 11 to 12 g. per cent, during the first six months after birth, and remaining at approximately this level up to about three years of age, after which there is a gradual increase until the age of 16 or so is reached. At this point, the hemoglobin content reaches a level which tends to be maintained throughout life; for males this level lies between roughly 14.5 and 16.0 g. per cent; for females, 13.5 and 15.0 g. per cent. As indicated on p. 613, the sex difference is due largely to differences in red cell count. This factor does not appear to explain the effect of age on hemoglobin content.

Aside from age and sex, other factors which influence the normal hemoglobin content include climate, altitude, exercise, menstruation, diurnal variation, and in general any factor which influences the red cell count or plasma volume. A *decreased* hemoglobin content is found in the various anemias, in pregnancy, after moderately severe or chronic hemorrhage, and following the excessive intake of fluids. An *increased* hemoglobin content, usually accompanied by an increase in red cell count (*polycythemia*) is found in hemoconcentration due to either shock or dehydration, in anoxia caused by either low oxygen pressure (high altitudes) or failure to properly oxygenate blood because of cardiac or pulmonary involvement, and experimentally after the administration of cobalt salts.

---

<sup>180</sup> For adaptation of the "acid hematin" method to chicken blood, see Schultze and Elvehjem: *J. Biol. Chem.*, **105**, 253 (1934).

**2. Method of Newcomer:**<sup>181</sup> **Principle.** The blood is treated with dilute hydrochloric acid to produce the brown "acid hematin" color described for the previous procedure. This is then matched in a colorimeter against a brown glass plate which has been spectrophotometrically standardized to correspond to the color obtained from a known amount of hemoglobin. This method is relatively little used, having been replaced by the various photometric procedures.

**3. Direct Photometric Method: Principle.** Blood is diluted in weakly alkaline solution. The color intensity is then measured in a photometer at 540 m $\mu$ , and the hemoglobin content estimated from the established reading of a blood of known hemoglobin content under similar conditions. In the procedure described here, very dilute ammonia solution is used for diluting the blood; 0.1 per cent sodium carbonate solution has also been proposed for this purpose.<sup>182</sup> If the diluted blood is treated before reading with a source of carbon monoxide gas, such as ordinary illuminating gas, the procedure becomes the more exact carbon monoxide hemoglobin method of Palmer.<sup>183</sup>

**Procedure.** Collect 0.02 ml. of blood in an accurate micropipet calibrated "to contain." Wipe off excess blood from the outside of the pipet, and transfer the blood to 5 ml. of dilute ammonium hydroxide solution<sup>184</sup> in a test tube. Rinse the pipet with the solution by filling and emptying several times. Mix, transfer to a suitable container if necessary, and read in the photometer at 540 m $\mu$ . Set the photometer to zero density with a blank of the dilute ammonia solution alone. For the Palmer procedure, bubble illuminating gas through the solution (in the hood) for about 30 seconds before reading in the photometer at 540 m $\mu$ .

**CALCULATION.** Density of Unknown  $\times F$  = grams hemoglobin per 100 ml. blood.  $F$  is a factor established by running the above-described procedure on a blood of known hemoglobin content. Obtain a sample of normal human blood and determine its hemoglobin content by either the gasometric method (Chapter 24) or, if gasometric equipment is not available, by the method of Wong described on p. 617. Treat duplicate or triplicate portions of this standard blood by the procedure described above. From the determined density and the hemoglobin content, calculate  $F$  as follows:

$$F = \frac{\text{Hemoglobin content, in g. per cent}}{\text{Density}}$$

Once established for a given photometer and filter or wavelength setting, the value of  $F$  will ordinarily be constant unless mechanical or other changes occur in the photometer. Checking the calibration at intervals will eliminate errors due to change in the value of  $F$ . In general, the calibration factor for one instrument and filter is not applicable to another instrument or filter, even of the same make.

At 540 m $\mu$ , and in a 1-cm. cuvette, a blood with 15.0 g. per cent hemoglobin has a density of approximately 0.500 when simply diluted as described; after carbon monoxide treatment, the density is approximately 0.550. For spectrophotometric data, see Fig. 110, p. 473. Beer's law is valid over the entire range of hemoglobin content apt to be encountered. For measurement using deeper cuvettes, measure the blood into 10 ml. of ammonia solution instead of 5 ml., establishing  $F$  on the same basis.

**Interpretation.** In the absence of significant amounts of abnormal blood pigments, both the simple dilution procedure and the Palmer

<sup>181</sup> Newcomer: *J. Biol. Chem.*, **37**, 465 (1919): 55, 569 (1923).

<sup>182</sup> Sanford, Sheard, and Osterberg: *Am. J. Clin. Path.*, **3**, 405 (1933).

<sup>183</sup> Palmer: *J. Biol. Chem.*, **33**, 119 (1918).

<sup>184</sup> Dilute 4 ml. of concentrated ammonium hydroxide to 1 liter with water and mix. Stable indefinitely.

method are known to give satisfactory results. The Palmer method is more accurate, since it is free from any error due to the presence of carbon monoxide hemoglobin in the blood as drawn. The chief disadvantage of the Palmer method in the past has been the difficulties associated with the preparation and maintenance of a suitable standard; this is eliminated by photometric calibration. The illuminating gas must of course be free from substances other than carbon monoxide which are capable of reacting with hemoglobin. If the blood contains significant amounts of methemoglobin, results will be in error. For the photometric determination of methemoglobin and total hemoglobin in the presence of methemoglobin, see the method of Evelyn and Malloy (p. 619). For other aspects of interpretation, see previous methods.

**4. Method of Wong.<sup>185</sup> Principle.** The iron is detached from the hemoglobin molecule by treatment with concentrated sulfuric acid in the presence of potassium persulfate, without heating. After removal of the proteins by tungstic acid, the iron in the filtrate is determined colorimetrically. From the total iron content, the hemoglobin content is readily obtained, since hemoglobin contains 0.34 per cent of iron, and only about 1 to 2 per cent or less of the total blood iron is nonhemoglobin iron.

**Procedure.<sup>186</sup>** With an Ostwald or micropipet, accurately transfer 0.5 ml. of well-mixed oxalated whole blood to a 50-ml. volumetric flask. Add 2 ml. of iron-free concentrated sulfuric acid. Mix by whirling one to two minutes. Add 2 ml. of saturated potassium persulfate solution. Mix and dilute to about 25 ml. with water. Add 2 ml. of 10 per cent sodium tungstate solution. Mix. Cool to room temperature under the tap, and dilute to volume with water. Stopper and mix by inversion. Filter through a dry paper, collecting the filtrate in a dry flask. Prepare a standard in a second 50-ml. volumetric flask by adding to about 25 ml. of water in the flask the following: 2 ml. of concentrated sulfuric acid, 2 ml. of saturated potassium persulfate solution, and 2.5 ml. of standard iron solution containing 0.1 mg.

<sup>185</sup> Wong: *J. Biol. Chem.*, **77**, 409 (1928). Hanzal (*Proc. Soc. Exptl. Biol. Med.*, **30**, 846 (1933)) uses sulfuric acid and hydrogen peroxide to effect complete oxidation of organic matter, followed by the thioglycollic acid colorimetric procedure described as an alternative method in the text. For a modification of the Wong method, claimed to be superior, see Ponder: *J. Biol. Chem.*, **144**, 333 (1942).

<sup>186</sup> Reagents Required: *Concentrated Sulfuric Acid*, iron-free.

*Saturated Potassium Persulfate Solution.* Shake 7 to 8 g. of reagent-grade iron-free potassium persulfate with 100 ml. of water in a glass-stoppered bottle. The undissolved excess settles to the bottom and compensates for loss by decomposition. Shake briefly before using. Keep in the refrigerator.

*10 Per Cent Sodium Tungstate Solution.* Dissolve 100 g. of reagent-grade iron-free sodium tungstate in water and dilute to 1 liter. Of the various reagents, it is most important that the tungstate be iron-free, since it is the only reagent whose iron content is not corrected for in photometric measurement by the use of a blank as described in the text.

*Standard Iron Solution.* Dissolve 0.702 g. of reagent-grade crystalline ferrous ammonium sulfate ("Mohr's salt") in 100 ml. of water. Add 5 ml. of concentrated sulfuric acid, warm slightly, and add concentrated potassium permanganate solution drop by drop until 1 drop produces a permanent color. Transfer to a 1-liter volumetric flask with rinsings, dilute to the mark, and mix. This solution contains 0.1 mg. of ferric iron per ml., and is stable indefinitely.

*3 N Potassium Thiocyanate Solution.* Dissolve 146 g. of reagent-grade potassium thiocyanate in water and dilute to 500 ml. Filter if turbid. Add 20 ml. of pure acetone to improve the keeping quality. Deterioration will be evidenced by the rapid formation of a yellow color in the blank test described in the procedure.

*Thioglycollic Acid.* Obtainable from Eastman Kodak Co., Rochester, New York.

*Concentrated Ammonium Hydroxide*, iron-free.

of ferric iron per ml. Cool to room temperature, dilute with water to the mark, and mix. For photometric measurement, prepare a blank similar to the standard except that the standard iron solution is omitted.

Measure 10 ml. of unknown filtrate, standard, and blank if necessary, into separate test tubes. To each add 0.5 ml. of saturated persulfate solution followed by 2 ml. of 3 N potassium thiocyanate solution. Mix by inversion and read in the colorimeter or photometer within the next 30 minutes. For photometric measurement, set the photometer to zero density with the blank, at 480  $m\mu$ .

An alternative procedure for color development using thioglycollic acid is as follows: To the 10-ml. portions in small flasks or test tubes as described above, add 0.1 ml. of thioglycollic acid,<sup>187</sup> and 2 ml. of concentrated ammonium hydroxide. Mix well, cool to room temperature by placing in cold water, and read in the colorimeter or photometer at any time within the next hour. Just before reading, shake again; the color may fade on prolonged standing but it can be immediately restored by shaking in air. For photometric measurement, set the photometer to zero density with the blank, at 540  $m\mu$ .

CALCULATION. For colorimetric measurement, using either the thiocyanate or thioglycollic acid procedure:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.25 \times \frac{100}{0.5} \times \frac{1}{3.4} = \text{grams hemoglobin per 100 ml. blood}$$

The value 1/3.4 represents the fact that 1 g. of hemoglobin contains 3.4 mg. of iron. If this factor is omitted in the calculations, the result gives *mg. of total iron* per 100 ml. of blood. Under ordinary circumstances, less than 2 per cent of the total blood iron is from sources other than hemoglobin; this nonhemoglobin iron is therefore neglected in the calculation of hemoglobin content, or a suitable correction may be made.

FIG. 164. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED IN WONG METHOD FOR IRON AND HEMOGLOBIN.

For standards containing (a) 1.25 mg., and (b) 2.5 mg. iron in 50 ml. Solution depth, 1 cm.

For photometric measurement, using either procedure:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.25 \times \frac{100}{0.5} \times \frac{1}{3.4} = \text{grams hemoglobin per 100 ml. blood}$$

The thiocyanate color has maximum absorption at about 480  $m\mu$ . (Fig. 164). At this

<sup>187</sup> Burmester (*J. Biol. Chem.*, **105**, 189 (1934) adds sodium sulfite solution prior to adding the thioglycollic acid, to reduce the persulfate. This does not appear to be necessary.

wavelength, and in a 1-cm. cuvette, the density of the standard described is approximately 0.750. Since the standard corresponds to a blood iron content of 50 mg. per cent, equivalent to 14.7 g. per cent hemoglobin, all values of hemoglobin ordinarily encountered may be satisfactorily determined under these conditions. With deeper cuvettes, use a 5-ml. aliquot of filtrate instead of 10 ml., add 5 ml. of the reagent blank solution used to set the photometer to zero density, develop and read the color as described, and multiply the results by 2. If a filter at 480 m $\mu$  is not available, equally satisfactory results at about 40 per cent lower scale reading may be obtained at 420 or 520 m $\mu$ .

The thioglycollic acid color has maximum absorption at 540 m $\mu$ . As compared to the thiocyanate color, the density of the standard under similar conditions is considerably less, being approximately 0.240 at peak absorption. This is not too low for accurate photometric measurement, however, and the color is superior in many respects to the thiocyanate color for analytical purposes. Excellent agreement with Beer's law is found up to double the standard concentration at almost any wavelength between 400 to 580 m $\mu$ . The only disadvantage appears to be a tendency of the color to fade on standing; as already mentioned, restoration to the original value is easily accomplished by brief shaking in air.

**Interpretation.** This method is recommended for standardization of other hemoglobin procedures in the absence of facilities for determining oxygen capacity. For other aspects of interpretation, see previous methods.

**5. Photometric Determination of Methemoglobin and Total Hemoglobin (Method of Evelyn and Malloy):**<sup>188</sup> **Principle.** Methemoglobin has a characteristic light absorption at 635 m $\mu$  (see Fig. 110, p. 473); this absorption is abolished in the presence of cyanide, which converts methemoglobin to cyanomethemoglobin. The difference in light absorption at 635 m $\mu$  before and after adding cyanide is a measure of the methemoglobin present. Total hemoglobin is determined by converting all the hemoglobin present to cyanomethemoglobin and measuring the light absorption at 540 m $\mu$ . Evelyn and Malloy also describe a procedure for measuring sulfhemoglobin with the same sample; this is omitted here because of the uncertainty associated with standardization. For details, see original article.

**Procedure.**<sup>189</sup> Transfer 0.1 ml. of capillary or well-mixed oxalated venous blood to a test tube containing 10 ml. of M/60 phosphate buffer at pH 6.6. Mix and allow to stand 5 minutes.

---

<sup>188</sup> Evelyn and Malloy: *J. Biol. Chem.*, **126**, 655 (1938).

<sup>189</sup> Reagents Required: M/15 Phosphate Buffer, pH 6.6. Dissolve 9 g. of Na<sub>2</sub>HPO<sub>4</sub>·12H<sub>2</sub>O and 5.7 g. of anhydrous KH<sub>2</sub>PO<sub>4</sub> in water and dilute to 1 liter.

M/60 Phosphate Buffer, pH 6.6. To 1 volume of M/15 phosphate buffer, pH 6.6, add 3 volumes of water, and mix.

20 Per Cent Potassium Ferricyanide. Dissolve 20 g. of reagent-grade potassium ferricyanide in water with the aid of heat, cool, and dilute to 100 ml. Dispense from a dropper bottle which delivers about 25 drops per ml. To prepare the 5 per cent solution, dilute 1 volume of the 20 per cent solution with 3 volumes of water.

10 Per Cent Sodium Cyanide. (Poisonous!) To 5 g. of reagent-grade sodium cyanide in a beaker, add 50 ml. of water, and stir to dissolve. Transfer to a dropping bottle for dispensing, as above.

Neutralized Sodium Cyanide. (Poisonous!) Mix 1 volume of 10 per cent sodium cyanide solution and 1 volume of 12 per cent acetic acid (12 ml. of glacial acetic acid diluted to 100 ml. with water). Add the acid to the cyanide (not the reverse) quickly with mixing, in the hood. Make only as much as will be used up within an hour, transferring it to a small dropping bottle for dispensing. Avoid exposure to vapors from the solution.

Concentrated Ammonium Hydroxide, in a dropping bottle as above.

(a) **METHEMOGLOBIN.** Determine the density of the solution in a photometer at 635  $m\mu$ , setting the photometer to zero density with water. This is reading  $D_1$ . Add 1 drop of neutralized sodium cyanide to the entire 10-ml. sample, mix, allow to stand 2 minutes, and make a second reading,  $D_2$ , under the same conditions as the first reading. The difference between  $D_1$  and  $D_2$  is the measure of the methemoglobin content which is calculated as described below. Any slight turbidity present is immaterial, since it is the same in both readings.

(b) **TOTAL HEMOGLOBIN.** Use either the sample treated with cyanide as just described, or the original 1:101 dilution of the blood if total hemoglobin alone is to be determined. Add 1 drop of concentrated ammonium hydroxide to the entire 10-ml. sample to clear it, mix, and transfer a 2-ml. portion to a test tube containing 8 ml. of M/15 phosphate buffer at pH 6.6 and 1 drop of 20 per cent potassium ferricyanide. Mix and allow to stand 2 minutes to convert hemoglobin to methemoglobin. Add 1 drop of 10 per cent sodium cyanide, mix, and again allow to stand 2 minutes for the formation of cyanomethemoglobin. Determine the density in the photometer at 540  $m\mu$ , setting the photometer to zero density with a blank consisting of 10 ml. of M/15 phosphate buffer plus 1 drop each of the ferricyanide and the sodium cyanide solutions. Let this reading be  $D_3$ .

CALCULATION. (a) *Methemoglobin.*

$$(D_1 - D_2) \times F_M = \text{grams methemoglobin per 100 ml. blood}$$

where  $F_M$  is a factor expressing the relationship between a known amount of methemoglobin and the change in density at 635  $m\mu$  after adding cyanide. This factor is established as described below.

(b) *Total Hemoglobin.*

$$D_3 \times F_T = \text{grams total hemoglobin per 100 ml. blood}$$

where  $F_T$  is the calibration factor for hemoglobin as cyanomethemoglobin, determined as described below.

**DETERMINATION OF CALIBRATION FACTORS.**<sup>190</sup> Obtain a sample of normal human blood and determine its hemoglobin content by either the gasometric method (Chapter 24) or the iron method of Wong (p. 617). Of the well-mixed blood, transfer 0.1 ml. to a tube containing 9.9 ml. of M/60 phosphate buffer at pH 6.6 and 0.1 ml. of 5 per cent potassium ferricyanide solution. Mix, allow to stand 2 minutes, and then determine the density ( $= D_1$ ) in the photometer at 635  $m\mu$ , setting to zero density with a blank consisting of 10 ml. of the phosphate buffer plus 0.1 ml. of the ferricyanide. After the reading has been made, add 1 drop of neutralized sodium cyanide solution to both the entire sample and blank, mix, and allow to stand 2 minutes, and again determine the density ( $= D_2$ ) against the blank, at the same wavelength. The factor  $F_M$  is calculated as follows:

$$\frac{\text{Hemoglobin content of blood, in g. per cent}}{(D_1 - D_2)} = F_M$$

To illustrate: in a 1-cm. cuvette under the conditions described, a blood of 15.2 g. per cent hemoglobin content gave a  $D_1$  reading of 0.357 and a  $D_2$  reading of 0.055.

<sup>190</sup> Evelyn and Malloy do not describe the obtaining of calibration factors, but give instead the numerical values for the various factors as established by them for the Evelyn photoelectric colorimeter. The factors given by Evelyn and Malloy may be employed under their conditions, but independent verification is suggested.

The factor is therefore

$$\frac{15.2}{(0.357 - 0.055)} = \frac{15.2}{0.302} = 50.4$$

To obtain  $F_T$ , dilute a 2-ml. portion of both the ferricyanide-cyanide treated standard and blank to 10 ml. with water and mix. Set the photometer to zero density at 540  $m\mu$  with the blank, and determine the density of the standard ( $= D_3$ ).

$$F_T = \frac{\text{Hemoglobin content of standard, in g. per cent}}{D_3}$$

To illustrate: the  $D_3$  reading for the blood containing 15.2 g. per cent hemoglobin was 0.211. Therefore  $F_T = 15.2/0.211 = 72.0$ .

Once they have been carefully established for a particular photometer and filter or wavelength setting, these factors should be valid indefinitely unless mechanical or other changes occur in the photometer. Checking at intervals will eliminate errors due to such changes.

**Interpretation.** The limit of precision of both the methemoglobin and total hemoglobin methods as described here is about 0.1–0.2 g. per cent. Using these methods with a Beckman spectrophotometer, in a study of 14 normal young men daily over a four-day period it was not possible to find even 0.1 g. per cent of methemoglobin in any except three random samples. Paul and Kemp,<sup>191</sup> using a similar procedure but at a lower dilution of blood (and therefore possibly increased sensitivity), claim that small amounts of methemoglobin (0.03 to 0.13 g. per cent) are regularly present in normal blood. Increased methemoglobin content (*methemoglobinemia*) is associated with the administration of a variety of drugs, such as nitrites, aniline and derivatives, sulfanilamide, acetanilide, etc. When the drug is discontinued, the methemoglobinemia begins to decrease; it is thought that methemoglobin can be converted back to hemoglobin in the red cell, hence any evident methemoglobinemia presumably represents a balance between rate of production and rate of reconversion to hemoglobin.<sup>192</sup>

The cyanomethemoglobin method for total hemoglobin is considered to be one of the most accurate of the colorimetric methods. Results will be slightly in error in the few instances where the relatively rare pigment *sulphemoglobin* is present; Evelyn and Malloy (*loc. cit.*) discuss this possibility of error and describe a correction for it. For further aspects of interpretation, see previous methods.

**Other Methods.** Hemoglobin may be quickly and accurately determined, along with the total plasma protein, by the copper sulfate-specific gravity method (p. 607). The use of pyridine hemochromogen has also been advocated as a basis for colorimetric or photometric measurement.<sup>193</sup> Among the advantages claimed is that the method may be accurately standardized using pure hemin. Ultramicromethods based on the benzidine color test for blood (see Chapter 22) have been described

<sup>191</sup> Paul and Kemp: *Proc. Soc. Exptl. Biol. Med.*, **56**, 55 (1944).

by Wu<sup>194</sup> and by Bing and Baker.<sup>195</sup> For the colorimetric determination of carbon monoxide hemoglobin, see p. 495. Gasometric procedures for the determination of hemoglobin, carbon monoxide hemoglobin, and methemoglobin are described in Chapter 24.

## DETERMINATION OF LACTIC ACID

**Introduction.** Blood lactic acid is ordinarily determined by conversion to acetaldehyde, which is then measured by titrimetric or colorimetric methods. A gasometric procedure based upon oxidation with permanganate to produce carbon dioxide has also been described.<sup>196</sup> Of the various methods, the colorimetric method described here is by far the most sensitive, being readily applicable to 0.1 ml. or less of blood. In obtaining blood for lactic acid determination, precautions must be observed against the conversion of blood glucose to lactic acid on standing (*glycolysis*). The use of fluoride as anticoagulant (see p. 541) will prevent glycolysis; if oxalate or heparin are used, the protein-free filtrate should be prepared as soon as possible after drawing the blood.<sup>197</sup>

**1. Method of Barker and Summerson:<sup>198</sup> Principle.** The glucose and other interfering material of the protein-free blood filtrate is removed by the Van Slyke-Salkowski method of treatment with copper sulfate and calcium hydroxide. An aliquot of the resulting solution is heated with concentrated sulfuric acid to convert lactic acid to acetaldehyde, which is then determined colorimetrically by reaction with *p*-hydroxydiphenyl in the presence of copper ions.

**Procedure.<sup>199</sup> Deproteinize the blood sample (whole blood, plasma) with either tungstic acid (p. 543), trichloroacetic acid (p. 631), or zinc hydroxide**

<sup>194</sup> Wu: *J. Biochemistry* (Japan), **2**, 189 (1922).

<sup>195</sup> Bing and Baker: *J. Biol. Chem.*, **92**, 589 (1931). See also McFarlane and Hamilton: *Biochem. J.*, **26**, 1050 (1932).

<sup>196</sup> Avery and Hastings: *J. Biol. Chem.*, **94**, 273 (1931).

<sup>197</sup> Friedemann and Haugen (*J. Biol. Chem.*, **144**, 67 (1942)) describe a procedure in which the drawn blood is ejected directly from the syringe into the protein-precipitating fluid.

<sup>198</sup> Barker and Summerson: *J. Biol. Chem.*, **138**, 535 (1941).

<sup>199</sup> Reagents Required: *20 Per Cent Copper Sulfate.* Dissolve 400 g. of  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  in about 1 liter of water with the aid of heat, cool, dilute to 2 liters, and mix. Stable indefinitely.

*4 Per Cent Copper Sulfate.* Dilute 1 volume of 20 per cent copper sulfate solution to 5 volumes with water and mix. Store in a bottle fitted with a stopper carrying a 1-ml. pipet which delivers approximately 20 drops per ml. If this is done, 1 drop may be used instead of the 0.05-ml. portion specified in the text.

*Calcium Hydroxide, Powder.* Either the U.S.P. or C.P. grades are satisfactory. It is conveniently dispensed with a spoon spatula known to hold approximately 1 g., since exact measurement is unimportant.

*Sulfuric Acid, Concentrated.* Reagent-grade iron-free sulfuric acid is satisfactory. It is dispensed from a buret, suitably protected against absorption of atmospheric moisture. The buret stopcock is cleaned thoroughly of grease and lubricated with a little of the acid itself. In delivering, precautions should be taken against error due to the slow drainage of the viscous acid. According to Russell (*J. Biol. Chem.*, **156**, 463 (1944)), nitrates and nitrites in the acid will interfere; only grades with low nitrate content are selected, and if a particular lot shows poor color development it is discarded.

*p-Hydroxydiphenyl Reagent.* Dissolve 1.5 g. of *p*-hydroxydiphenyl (obtainable from Eastman Kodak Co., Rochester, N.Y.) in 10 ml. of 5 per cent sodium hydroxide solution, plus a little water, by warming and stirring, and dilute to 100 ml. with water. Store in a brown bottle fitted with a stopper and pipet capable of delivering 20 drops per ml. If this is done, 2 drops may be used instead of the 0.1-ml. portion specified in the text. The reagent is stable for many months; deterioration is evidenced by high blank readings.

*Standard Lactic Acid Solution.* This is prepared preferably from lithium lactate, which is

(p. 572) at a 1:10 dilution. Transfer 2 ml. of the protein-free filtrate, representing 0.2 ml. of blood, to a centrifuge tube graduated at 10 ml. In a second similar tube place 5 ml. of standard lactic acid solution, containing 0.01 mg. of lactic acid per ml. In a third tube place a little water; this is a blank, and serves to control the small amount of color yielded by the reagents alone. To each tube add 1 ml. of 20 per cent copper sulfate solution and dilute to the 10-ml. mark with water. Add 1 g. of powdered calcium hydroxide to each tube, stopper,<sup>200</sup> and shake vigorously until the solids are uniformly dispersed. Allow to stand for one-half hour, repeating the shaking at least once in the interim. Centrifuge down the precipitate, and transfer duplicate 1-ml. portions of the supernatant from each tube to thoroughly clean and dry test tubes having an internal diameter of 18 to 23 mm.<sup>201</sup> To each tube add 0.05 ml. of 4 per cent copper sulfate solution, followed by 6 ml. of concentrated sulfuric acid from a buret. The sulfuric acid should be added drop by drop at first, mixing the contents of the tube well during the addition. The tube contents will become hot; it is not necessary to cool the tube. After the acid has been added to all the tubes, place them upright in boiling water for 5 minutes, then transfer the tubes to cold water (preferably running) and cool to 20° C. or below. When the contents of the tubes are sufficiently cool (but not before) add 0.1 ml. of the *p*-hydroxydiphenyl reagent, drop by drop, to each tube. The reagent precipitates out on entering the concentrated acid; it is dispersed throughout the solution as quickly and uniformly as possible by lateral shaking. When the reagent has been added, place the tubes in a beaker of water at 30° C. and allow to stand for 30 minutes or longer. Redisperse the precipitated reagent at least once during this period. Finally place the tubes in vigorously boiling water for exactly 90 seconds, remove, and cool in cold water to room temperature. Transfer the colored solutions to suitable containers and determine the photometric density at 560 m $\mu$ , using water for setting the photometer at zero density.

CALCULATION. Average the duplicate results on the blank to obtain the blank density. Subtract this value from the averages of standard and unknown to obtain their true densities. Since the 1-ml. portion of copper-lime supernatant used for color development contains 0.005 mg. of lactic acid in the case of the standard, and this represents 0.02 ml. of original blood in the unknown (i.e., a dilution of 50), the calculation in this case is as follows:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.005 \times 50 \times 100 = \text{mg. lactic acid per 100 ml. blood}$$

anhydrous. (For the method of preparing pure lithium lactate, see Chapter 31). For the stock standard, dissolve 0.213 g. of pure dry lithium lactate in about 100 ml. of water in a 1-liter volumetric flask, add about 1 ml. of concentrated sulfuric acid, dilute to the mark with water, and mix. This solution contains 1 mg. of lactic acid in 5 ml., and is stable indefinitely if kept in the refrigerator. To prepare the working standard, dilute 5 ml. of stock standard to 100 ml. in a glass-stoppered volumetric flask with water and mix. This solution contains 0.01 mg. of lactic acid per ml., and is best prepared fresh daily.

<sup>200</sup> Glass-stoppered tubes may be used or, if these are unavailable, cover the mouth of the tube with a small square of "Parafilm," fresh surface down, held in place by the finger tip. "Parafilm" may be obtained from laboratory supply houses. In this and other phases of the procedure, contact of the solutions with the skin must be avoided because of the possibility of contamination with lactic acid from the skin surfaces.

<sup>201</sup> Wide test tubes are specified to facilitate thorough mixing by lateral shaking; this is more important than usual because of the viscosity of the concentrated acid used as solvent. After use, the tubes are best cleaned by simply rinsing in hot tap water, followed by distilled water, and drying by drainage or in an oven. None of the glassware used in this procedure should be cleaned with chromic acid cleaning mixture. Hot soapy water followed by thorough rinsing with distilled water is adequate.

It is recommended that the average blank density be determined separately as described to minimize error due to possible variation in the blank. If desired, a single blank tube may be run and used for setting the photometer to zero density, in which case the average measured densities of standard and unknown are used directly in the calculation. The blank color is ordinarily about 10 per cent of the standard color. In a 1-cm. cuvette, at 560  $m\mu$ , the standard described (equivalent to 25 mg. per cent blood lactic acid) has a density of approximately 0.400 (Fig. 165) and up to 60 mg. per cent blood lactic acid may be accurately determined. For higher values, or with deeper cuvettes, use smaller aliquots of filtrate and standard for the copper-lime treatment but keep the final volume at 10 ml. at this stage, using the same amounts of 20 per cent copper sulfate solution and calcium hydroxide as described. Correct the calculations as necessary.

FIG. 165. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED IN BARKER-SUMMERSON LACTIC ACID METHOD.

For standards containing (a) 0.002 mg., and (b) 0.004 mg. lactic acid. Solution depth, 1 cm.

**Interpretation.** Venous blood of normal individuals in the resting state contains 5 to 20 mg. of lactic acid per 100 ml.<sup>202</sup> During severe exercise this may rise to well over 100 mg. per cent, decreasing rapidly during recovery. Pathologically, increased blood lactate content is noted in general whenever there is a deficient supply of oxygen to the tissues (pneumonia, heart failure) or the organism is unable to maintain the normal equilibrium between lactate production and utilization, as after the administration of anesthetics and in liver disease. Usually the presence of excessive amounts of blood lactate is at the expense of equivalent amounts of blood bicarbonate, and an acidosis results. This disappears as the lactate is utilized.

**2. Method of Friedemann and Graeser:<sup>203</sup> Principle.** The glucose of blood filtrates is removed with copper sulfate and calcium hydroxide, the lactic acid converted to acetaldehyde, which is then combined with sodium bisulfite. The bound sulfite is determined iodometrically, as in the method for urine (see p. 916).

**Procedure.** To 10 ml. of Folin-Wu or Somogyi filtrate representing 1 ml. of blood add 2 ml. of 10 per cent  $\text{CuSO}_4$  and 2 ml. of 5 per cent suspension of

<sup>202</sup> To convert mg. per cent lactic acid into milliequivalents per liter, divide by 9.0.

<sup>203</sup> Friedemann and Graeser: *J. Biol. Chem.*, **100**, 291 (1933). See also Wendel: *J. Biol. Chem.*, **102**, 47 (1933); Edwards: *ibid.*, **125**, 571 (1938).

**Ca(OH)<sub>2</sub>.** Shake at intervals for one-half hour and centrifuge. Of the filtrate 5-ml. duplicates are taken for analysis as in the method for urine (page 916) using 0.002 N iodine. For the blank treat 10 ml. of 0.1 per cent glucose in the same manner as blood filtrate.

**Interpretation.** See the previous method.

### **Determination of Lactic Acid in Tissues, Tissue Extracts, Etc.**

Either of the procedures described above is suitable for the determination of the lactic acid content of various types of biological material. For tissue analysis, precautions must be taken against post-mortem changes in lactic acid content, by prompt freezing in solid carbon dioxide ("dry ice") or by adequate treatment with acid to destroy enzyme systems present. Proteins present may be removed by any of the common methods. For the colorimetric procedure, an aliquot of the protein-free fluid containing 0.02 to 0.10 mg. of lactic acid is treated by the copper-lime procedure described at a volume of 10 ml., and 1 ml. of supernatant is analyzed as described for blood. For the iodometric procedure, the aliquot should contain about 0.5 mg. of lactic acid. This is diluted to 10 ml. and treated as described for blood.

## **DETERMINATION OF CHLORIDES**

**Introduction.** The chlorides of whole blood are distributed to the extent of about one-third of the total in the red cells and two-thirds in the plasma. Plasma or serum is therefore ordinarily used for analysis; if whole blood were used, variations in red cell content would affect results out of proportion to their clinical significance. In obtaining plasma, excessive amounts of anticoagulants such as oxalate must be avoided, since they influence water and chloride distribution between cells and plasma; heparin does not have this effect. For precise work, where small changes in chloride content are of significance, blood should be collected under oil to minimize changes in carbon dioxide tension, since this also affects chloride distribution between cells and plasma (*chloride shift*, see "Role of the Red Cells," Chapter 24). This precaution is not necessary in routine clinical practice, but it is important that measurements be made carefully, preferably using volumetric flasks for dilution as in the preparation of protein-free filtrates, because of the high chloride content of plasma or serum and the slight variations which are of significance.

Chloride content is commonly expressed in terms of milligrams of sodium chloride per 100 ml. of sample. It is more exact, and preferable, to express chloride concentration in terms of milliequivalents of chloride per liter, since the major functions of chloride in the body are concerned with osmotic pressure regulation and acid-base balance. One milliequivalent of chloride ion corresponds to 35.5 mg., or 58.5 mg. of sodium chloride. A plasma with a chloride concentration of 585 mg. per cent expressed as sodium chloride therefore contains 100 milliequivalents of chloride per liter. The general relationship between these two methods of expressing chloride content is as follows:

$$\begin{aligned} \text{milliequivalents of chloride per liter} &\times 5.85 \\ &= \text{mg. chloride as sodium chloride per 100 ml.} \end{aligned}$$

**1. Method of Whitehorn.<sup>204</sup> Principle.** The chlorides are precipitated from the blood filtrate by means of silver nitrate in the presence of nitric acid, and the excess of silver titrated with standard thiocyanate solution, using ferric ammonium sulfate as an indicator.

**Procedure.<sup>205</sup>** Pipet 10 ml. of the Folin-Wu filtrate into a porcelain dish. Add with a pipet 5 ml. of the standard silver nitrate solution and stir thoroughly. Add about 5 ml. of concentrated nitric acid (sp. gr. 1.42), mix, and let stand for 5 minutes, to permit the flocking out of the silver chloride. Then add with a spatula about 0.3 g. of powdered ferric ammonium sulfate and titrate the excess of silver nitrate with the standard thiocyanate solution until the definite salmon-red (not yellow) color of the ferric thiocyanate persists in spite of vigorous shaking for at least 15 seconds. A microburet should be used in the titration.

**CALCULATION.** Subtract the number of ml. of thiocyanate required from 5.00 (= ml. of silver nitrate added) and multiply the result by 100 to obtain the chloride content expressed as mg. of sodium chloride per 100 ml. To express results in terms of milliequivalents of chloride per liter, calculate as above and divide the result by 5.85.

**Interpretation.** Plasma or serum normally contains from 570 to 620 mg. per 100 ml., expressed as sodium chloride, or 98 to 106 milliequivalents of chloride per liter. The corresponding figures for whole blood are 450 to 500 mg. per cent, or 77 to 86 milliequivalents per liter. Increased plasma chloride is noted in nephritis, and this determination may aid in deciding whether or not salt should be restricted in the diet. Decreased plasma chloride may occur in gastrointestinal disturbances associated with vomiting or diarrhea, in pneumonia, and in Addison's disease. Because of the close association between water and chloride, marked disturbances in water distribution (hydration, dehydration) may not necessarily be accompanied by changes from the normal plasma chloride level.

**2. Method of Schales and Schales:<sup>206</sup> Principle.** The sample is titrated with standard mercuric nitrate solution at the proper acidity in the presence of diphenylcarbazone as indicator. Chlorides present react with the added mercuric ions to form soluble but undissociated mercuric chloride. When an excess of mercuric ion has been added, the indicator turns purple. The end point is sharp and relatively stable.

**Procedure.<sup>207</sup>** Transfer 2 ml. of Folin-Wu filtrate of plasma or serum (equivalent to 0.2 ml. of original sample) to a small flask, and add 0.06 ml. (4 drops)

<sup>204</sup> Whitehorn: *J. Biol. Chem.*, **45**, 449 (1921).

<sup>205</sup> Reagents Required: *Standard Silver Nitrate Solution.* Dissolve 2.905 g. of c.p. silver nitrate in distilled water. Transfer this solution to a liter volumetric flask and make up to the mark with distilled water. Mix thoroughly and preserve in a brown bottle. 1 ml. = 1 mg. NaCl. (It is to be noted that the silver nitrate and nitric acid are not added to the protein-free filtrate simultaneously. To do so may result in the mechanical enclosure of silver nitrate solution within the curds, and hence too high results.)

*Standard Thiocyanate Solution.* Because thiocyanates are hygroscopic, the standard solution should be prepared volumetrically. Dissolve about 1.7 g. of KCNS or 1.4 g. of NH<sub>4</sub>CNS in a liter of water. Titrate against standard silver nitrate solution under the conditions specified under "Procedure," and dilute accurately so that 5 ml. are equivalent to 5 ml. of the silver nitrate solution.

Solid ferric alum is used rather than a solution, in order to insure a very high concentration in the mixture to be titrated. It is powdered to facilitate its solution.

<sup>206</sup> Schales and Schales: *J. Biol. Chem.*, **140**, 879 (1941).

<sup>207</sup> Reagents Required: *Diphenylcarbazone Solution.* Dissolve 100 mg. of *s*-diphenylcarba-

of diphenylcarbazone indicator solution. Titrate with the standard mercuric nitrate solution, using a microburet capable of being read to 0.01 ml. and delivering small drops. At the end point, the color of the solution changes from light yellow to deep purple.

The plasma or serum may be titrated directly without previous deproteinization. This procedure eliminates errors in the preparation of the filtrate. Transfer 0.2 ml. of sample to a small flask, add 1.8 ml. of water, 0.06 ml. of indicator, and titrate as above. The color of the solution undergoes several changes during the titration, becoming light yellow just before the end point is reached, and changing to pale violet at the end point. Results by the direct titration are slightly higher than when a filtrate is used, possibly because of slight loss of chloride during deproteinization.

CALCULATION. Results for either the protein-free or direct titration are calculated as follows:

$$\text{ml. mercuric nitrate solution used} \times \frac{100}{A} = \text{milliequivalents chloride per liter}$$

where  $A$  equals the number of ml. of mercuric nitrate solution required for 2 ml. of standard sodium chloride solution. If  $A$  equals 2.00, the calculation simplifies to:

$$\text{ml. mercuric nitrate solution used} \times 50 = \text{milliequivalents of chloride per liter}$$

If results are desired in terms of mg. of sodium chloride per 100 ml., the calculation is as follows:

$$\text{ml. mercuric nitrate solution used} \times \frac{100}{A} \times 5.85 = \text{mg. NaCl per 100 ml.}$$

**Interpretation.** See the previous method. This method, though not quite so accurate as the iodometric method described subsequently, is relatively simple and is known to give satisfactory results. It has definite advantages over the Whitehorn method. It may be applied to spinal fluid analyses, ordinarily without deproteinization. For the application to urine, see Asper, Schales, and Schales.<sup>208</sup>

**3. Method of Sendroy, Modified by Van Slyke and Hiller:<sup>209</sup> Principle.** The plasma or serum is treated with phosphoric acid containing either tungstic acid or

zone (obtainable from Eastman Kodak Co., Rochester, N.Y.) in 95 per cent alcohol, and dilute to 100 ml. Store in a dark bottle in the cold. Equip the bottle with a rubber-bulb medicine dropper whose tip is adjusted so as to deliver 65 to 70 drops of solution per ml. Prepare fresh solution each month.

**Standard Sodium Chloride Solution.** Dry some reagent-grade sodium chloride in an oven at 110° to 120° C. overnight. Cool and weigh out 584.5 mg. Dissolve in a little water and transfer with rinsings to a 1-liter volumetric flask. Dilute to the mark with water and mix. This solution is stable indefinitely, and contains 10 milliequivalents of chloride per liter, or 58.45 mg. of sodium chloride per 100 ml. It is used to standardize each new lot of standard mercuric nitrate solution.

**Standard Mercuric Nitrate Solution.** Place a few hundred ml. of water in a 1-liter volumetric flask and add 20 ml. of 2 N nitric acid. Add 3 g. of reagent-grade mercuric nitrate, dissolve by shaking, dilute to volume with water, and mix. Standardize as follows: transfer 2 ml. of standard sodium chloride solution to a small flask, add 4 drops of diphenylcarbazone solution, and titrate with the mercuric nitrate solution from a microburet as described in the text. The number of ml. of mercuric nitrate solution required equals the value  $A$  used in the calculations above. If the strength of the mercuric nitrate solution is adjusted so that  $A$  equals 2.00, either by adding more mercuric nitrate or by dilution with water containing 20 ml. of 2 N nitric acid per liter, as the case may be, the calculations are simplified (see text). This standard mercuric nitrate solution is stable indefinitely, and need not be protected from light, so that large amounts may be prepared at one time.

<sup>208</sup> *J. Biol. Chem.*, **168**, 779 (1947).

<sup>209</sup> Sendroy: *J. Biol. Chem.*, **120**, 335, 405, 419 (1937); *ibid.*, **130**, 605 (1939); *ibid.*, **142**, 171 (1942). Van Slyke and Hiller (personal communication).

picric acid, which precipitates the proteins. The mixture is then shaken with an excess of solid silver iodate and filtered. Chlorides present react with the insoluble silver iodate to form insoluble silver chloride and soluble iodate, which passes into the filtrate. On the addition of iodide to the filtrate, the iodate reacts to produce free iodine, which is then titrated with standard thiosulfate.

**Procedure.**<sup>210</sup> Transfer 1 ml. of plasma or serum to a 50 ml. Erlenmeyer flask. Add 25 ml. of phosphoric-tungstic acid or phosphoric-picric acid solution and mix. To the mixture add 0.3 to 0.5 g. of silver iodate (measured with sufficient accuracy from a spoon spatula previously found to contain approximately the right amount). Stopper the flask and shake vigorously for 30 seconds. Pour onto a dry 9-cm. folded filter of loose texture, collecting the filtrate in a dry flask.

---

<sup>210</sup> Reagents Required: *Phosphoric-Tungstic Acid Solution*. Transfer 6 g. of reagent-grade chloride-free sodium tungstate to a 1-liter volumetric flask, add water to dissolve, followed by 10 ml. of reagent-grade phosphoric acid, make up to 1 liter with water, and mix. Tungstate may be tested for chloride by dissolving 1 g. in 10 ml. of water, adding 20 ml. of concentrated nitric acid, and filtering into a test tube containing a few ml. of 1 per cent silver nitrate. If the filtrate does not show a precipitate of silver chloride, the tungstate is chloride-free. Tungstate may be freed from chloride by treating a hot concentrated solution with an equal volume of 95 per cent alcohol, filtering off the crystals from the cooled solution, washing with alcohol, and drying in air.

*Phosphoric-Picric Acid Solution*. This may be used in place of the tungstic acid reagent if chloride-free tungstate is not obtainable; picric acid is less likely to contain chloride. Place 6 ml. of phosphoric acid and 2 g. of picric acid in a 1-liter flask, add water to dissolve, dilute to 1 liter, and mix.

*Silver Iodate*. This must be free from more soluble iodates. To test, shake 0.5 g. with 25 ml. of phosphoric-tungstic acid solution for 1 minute, filter, and titrate 10 ml. of filtrate with 0.02308 N thiosulfate, after adding iodide, as described above for plasma filtrates. If more than 0.50 ml. of thiosulfate is required at a temperature of 20° C., or 1.00 ml. at 40°, with approximately linear variation at intermediate temperatures, the iodate is not pure enough. To prepare pure silver iodate, dissolve 42.8 g. of potassium iodate in a liter of water and add to it with stirring a liter of silver nitrate solution containing 34 g. of silver nitrate. Filter off the precipitated silver iodate by suction, and wash with water until a 10-ml. portion of the washings when titrated with thiosulfate in the presence of iodide as described above requires no more thiosulfate than corresponds to the solubility of silver iodate as indicated above. Stir up the washed precipitate in 500 ml. of water, suck dry on the Buchner funnel, transfer to a vacuum desiccator to dry thoroughly, and store in a brown bottle.

*Sodium Iodide Solution*. Dissolve 50 g. of reagent-grade sodium iodide in 50 ml. of water. Store in a brown bottle. This solution must be discarded when a 1-ml. portion added to 10 ml. of phosphoric-tungstic acid solution gives a blue color in the presence of a drop of starch solution. For occasional analyses the dry reagent is more economical. A 0.5-g. portion is used for each analysis. Dispense from a spoon spatula previously found to deliver approximately the right amount.

*Standard Sodium Thiosulfate Solution*. Prepare a stock thiosulfate solution by dissolving 57.3 g. of crystalline sodium thiosulfate,  $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$ , in water, diluting to 250 ml. in a volumetric flask, and mixing. This solution is stable indefinitely. To prepare the thiosulfate solution used in the titration, transfer 25 ml. of stock solution to a 1-liter volumetric flask, add 1 g. of borax as preservative, dilute to volume with water, and mix. This solution should be 0.02308 N. Standardize as follows: prepare a standard 0.1 N iodate solution by dissolving 3.567 g. of pure potassium iodate in water and diluting to 1 liter. This solution is stable indefinitely. Transfer 5 ml. to a small flask, add about 20 ml. of water and 1 ml. of 1 N acid (sulfuric or hydrochloric). Add 1.5 ml. of sodium iodide solution and titrate immediately with the thiosulfate solution, using starch as indicator. If the volume of thiosulfate required is 21.67 ml., the thiosulfate is 0.02308 N and is used without a factor as described in the procedure above. If some other volume of thiosulfate is required, the factor is obtained by dividing 21.67 by the volume of thiosulfate required. Thus, if 22.40 ml. of thiosulfate were used for titrating the 5 ml. of standard iodate, the factor is  $21.67/22.40$ , or 0.967. This factor is then used in the calculations as described in the procedure. The dilute thiosulfate solution undergoes slow deterioration over a period of months. It should be checked at intervals against the standard iodate solution and a new factor obtained if necessary.

Transfer 10 ml. of the water-clear filtrate to a small flask. Add 1 ml. of sodium iodide solution (or 0.5 g. of solid sodium iodide). Mix carefully with one or two swirls, and titrate the liberated iodine immediately with standard sodium thiosulfate solution. Add the thiosulfate in rapid drops, with careful mixing, until the yellow color of the iodine has almost disappeared. Add 2 drops of starch solution and continue titration until the blue color disappears and the solution is colorless, or, if picric acid was used for deproteinization, only the yellow color of the picric acid remains.

**CALCULATION.** In this procedure, 1 equivalent of chloride ion leads to the production of 6 equivalents of iodine, requiring 6 equivalents of thiosulfate for titration. Therefore 1 ml. of N thiosulfate represents  $\frac{1}{6}$  milliequivalent of chloride. Since the 10 ml. of filtrate titrated represent  $1\frac{0}{26}$  ml. of sample, the formula for calculation of results in terms of milliequivalents of chloride per liter is as follows:

$$\text{ml. thiosulfate} \times \text{normality} \times \frac{1}{6} \times 2\frac{6}{10} \times 1000 = \text{milliequivalents chloride per liter}$$

If the normality of the thiosulfate is exactly 0.02308, the calculation simplifies to:

$$\text{ml. thiosulfate} \times 10 = \text{milliequivalents chloride per liter}$$

If the thiosulfate is not exactly 0.02308 N and a factor is used as described under "Standardization," the calculation becomes:

$$\text{ml. thiosulfate} \times \text{factor} \times 10 = \text{milliequivalents chloride per liter}$$

To express results on the basis of milligrams of NaCl per 100 ml., since 1 milliequivalent of chloride corresponds to 58.5 mg. of NaCl, the calculations become:

$$\text{ml. 0.02308 N thiosulfate} \times 58.5 = \text{mg. NaCl per 100 ml.}$$

or

$$\text{ml. thiosulfate} \times \text{factor} \times 58.5 = \text{mg. NaCl per 100 ml.}$$

**Interpretation.** See under the method of Whitehorn above. This method may be used with Folin-Wu filtrates (10 ml. of filtrate made up to 26 ml. with phosphoric-tungstic reagent, treated with iodate, filtered, and titrated exactly as described above, with the same calculations); it is directly applicable on an unchanged basis to the analysis of spinal fluid, gastric contents, urine, etc., and it may be used on a microscale with proportionate decrease in amounts of reagents used, and suitable change in calculations.

**4. Determination of Total Chlorides in Blood and Tissues (Van Slyke):**<sup>211</sup>  
**Principle.** The proteins are oxidized, and the chloride is precipitated, by wet digestion with concentrated nitric acid in the presence of silver nitrate. The excess silver is then titrated with thiocyanate, as described in Whitehorn's method.

## DETERMINATION OF PHOSPHORUS

**Partition of Blood Phosphorus.** Whole blood contains about 40 mg. of total phosphorus per 100 ml., present chiefly as *inorganic phosphate*, *organic acid-soluble phosphate esters*, and *lipide-phosphorus*, with other phosphate-containing compounds possibly present in small amounts. The distribution of phosphorus between cells and plasma is quite uneven;

<sup>211</sup> Van Slyke: *J. Biol. Chem.*, 58, 523 (1923); Wilson and Ball: *J. Biol. Chem.*, 79, 221 (1928).

for example, cells contain much more organic and total phosphate than plasma, while the inorganic phosphate of whole blood is practically entirely in the plasma. For the determination of inorganic phosphate and total acid-soluble phosphorus, protein is precipitated with trichloroacetic acid and the filtrate used. For lipide phosphorus determination, an alcohol-ether extract is obtained. In the determination of total acid-soluble, lipide, and total phosphorus, organic matter is destroyed by digestion with sulfuric acid and 30 per cent hydrogen peroxide. The phosphate-containing solutions thus obtained (as well as the trichloroacetic acid filtrate used for the direct determination of inorganic phosphate) are treated with molybdic acid, whereby phosphomolybdic acid is formed from any inorganic phosphate present. On the addition of suitable reducing agents, phosphomolybdic acid is selectively reduced to yield a deep blue color ("molybdenum blue") which is apparently a mixture of lower oxides of molybdenum. This color is used as a measure of the amount of phosphate present.

Bell and Doisy<sup>212</sup> carried out the reduction with hydroquinone in alkaline solution. Briggs<sup>213</sup> made the color more stable by using an acid solution. Benedict and Theis<sup>214</sup> intensified the color by heating. This procedure is satisfactory where only inorganic phosphate is present, as in serum or plasma filtrates, but cannot be used on whole blood filtrates for example, since any phosphate esters present may be hydrolyzed by the heating in acid and thus lead to high values. Fiske and SubbaRow<sup>215</sup> suggested the use of 1,2,4-aminonaphtholsulfonic acid as reducing agent, at room temperature. This method has been widely used, and is the one described here. Kuttner and Cohen<sup>216</sup> revived the original suggestion of Denigès that stannous chloride be used as reducing agent, and this has likewise found much favor. Stannous chloride has the advantage over aminonaphtholsulfonic acid that the stock reagent is quite stable and the color produced with phosphomolybdate is more intense, thus permitting the estimation of smaller amounts of phosphorus. For example, Shinowara, Jones, and Reinhart<sup>217</sup> have described procedures for phosphate determination, using stannous chloride as reducing agent, which require as little as 0.06 ml. of serum. A disadvantage of stannous chloride is that the color intensity changes continuously with time, so that careful control of the time factor is essential, and deviations from Beer's law are found, usually requiring correction factors. In the authors' experience, the method of Fiske and SubbaRow has proved superior to any other method thus far described.

**1. Determination of Inorganic Phosphate (Method of Fiske and SubbaRow<sup>215</sup>): Principle.** The proteins of blood are precipitated with trichloroacetic acid. The protein-free filtrate is treated with an acid molybdate solution, which forms phos-

---

<sup>213</sup> Briggs: *J. Biol. Chem.*, **53**, 13 (1922); **59**, 255 (1924).

<sup>214</sup> Benedict and Theis: *J. Biol. Chem.*, **61**, 63 (1924).

<sup>215</sup> Fiske and SubbaRow: *J. Biol. Chem.*, **66**, 375 (1925).

<sup>216</sup> Kuttner and Cohen: *J. Biol. Chem.*, **75**, 517 (1927); also Kuttner and Lichtenstein: *J. Biol. Chem.*, **86**, 671 (1930).

<sup>217</sup> Shinowara, Jones, and Reinhart: *J. Biol. Chem.*, **142**, 921 (1942).

phomolybdic acid from any phosphate present. The phosphomolybdic acid is reduced by the addition of 1,2,4-aminonaphtholsulfonic acid reagent, to produce a blue color whose intensity is proportional to the amount of phosphate present.

**Procedure.**<sup>218</sup> To 8 ml. of 10 per cent trichloroacetic acid solution in a small flask, add slowly, with mixing, 2 ml. of whole blood, serum, or plasma. Stopper, shake, and filter through a low-ash filter paper. Transfer 5 ml. of filtrate to a cylinder or other container graduated at 10 ml., and add 1 ml. of the Molybdate II reagent. Mix. Add 0.4 ml. of aminonaphtholsulfonic acid reagent, and again mix. Dilute to the mark, mix, and allow to stand 5 minutes.

For colorimetric measurement, compare in the colorimeter against a standard prepared at the same time, as follows: Transfer 5 ml. of standard phosphate solution, containing 0.4 mg. of phosphorus, to a 100-ml. volumetric flask, and add from a graduate 50 ml. of water. Add 10 ml. of Molybdate I (*not* Molybdate II), mix, and add 4 ml. of aminonaphtholsulfonic acid reagent. Dilute with water to the 100 ml. mark, mix, and allow to stand 5 minutes. Compare the standard against itself in the colorimeter before reading the unknown. If the color of the unknown is particularly strong, repeat the reading of the unknown a few minutes later, to be sure that maximal color development has taken place.

For photometric measurement, transfer a portion of the colored solution to a suitable container and read in the photometer at 660 to 720  $m\mu$  (see Fig. 166). Set the photometer to zero density with a blank prepared by treating 5 ml. of 10 per cent trichloroacetic acid with 1 ml. of Molybdate II and 0.4 ml. of aminonaphtholsulfonic acid reagent, followed by water to a volume of 10 ml. Establish the density of a standard phosphate solution as follows: Transfer 5 ml. of the stock phosphate standard, containing 0.4 mg. of P, to a 50-ml. volumetric flask, make up to volume with 10 per cent trichloroacetic acid, and mix. Transfer 5 ml. of this dilute standard, containing 0.04 mg. of phosphorus, to a suitable container, add 1 ml. of Molybdate II

---

<sup>218</sup> Reagents Required: *10 Per Cent Trichloroacetic Acid*. Dissolve 10 g. of reagent-grade trichloroacetic acid in water and dilute to 100 ml.

*10 N Sulfuric Acid*. Carefully add 450 ml. of concentrated sulfuric acid to 1300 ml. of water. To check, dilute 10 ml. of this solution to 100 ml. in a volumetric flask, mix, and titrate a 10-ml. portion with standard 1 N sodium hydroxide. From the titration results, adjust the original solution if necessary to make it exactly 10 N.

*Molybdate I*. Dissolve 25 g. of reagent-grade ammonium molybdate in about 200 ml. of water. In a 1-liter volumetric flask place 500 ml. of 10 N sulfuric acid. Add the molybdate solution and dilute with washings to 1 liter with water. Mix. Stable indefinitely.

*Molybdate II*. Dissolve 25 g. of reagent-grade ammonium molybdate in about 200 ml. of water. In a 1-liter volumetric flask place 300 ml. of 10 N sulfuric acid. Add the molybdate solution and dilute with washings to 1 liter with water. Mix. Stable indefinitely.

*Aminonaphtholsulfonic Acid Reagent*. Place 195 ml. of 15 per cent sodium bisulfite solution (see below) in a glass-stoppered cylinder. Add 0.5 g. of 1,2,4-aminonaphtholsulfonic acid (satisfactory material can be obtained from Eastman Kodak Co., Rochester, N.Y.). Add 5 ml. of 20 per cent sodium sulfite (see below). Stopper and shake until the powder is dissolved. If solution is not complete, add more sodium sulfite, 1 ml. at a time, with shaking, but avoid an excess. Transfer the solution to a brown-glass bottle and store in the cold. This solution is usable for about four weeks, if kept as described.

*15 Per Cent Sodium Bisulfite*. To 30 g. of reagent-grade sodium bisulfite in a beaker add 200 ml. of water from a graduated cylinder. Stir to dissolve, and if turbid allow to stand well-stoppered for several days and filter. Keep well-stoppered.

*20 Per Cent Sodium Sulfite*. Dissolve 20 g. of reagent-grade anhydrous sodium sulfite in water, dilute to 100 ml., and filter if necessary. Keep well-stoppered.

*Standard Phosphate Solution*. Dissolve exactly 0.351 g. of pure dry monopotassium phosphate in water and transfer quantitatively to a 1-liter volumetric flask. Add 10 ml. of 10 N sulfuric acid, dilute to the mark with water, and mix. This solution contains 0.4 mg. of phosphorus in 5 ml. It is stable indefinitely.
